3/1/2020

Abstract

We derive the dynamics of the distribution of a quantitative character and the abundance of a biological population from a stochastic partial differential equation driven by space-time white noise. In the process we develop a useful set of heuristics to operationalize the powerful, but abstract theory of white noise and measure-valued stochastic processes. This approach allows us to compute the full implications of demographic stochasticity on phenotypic distributions and abundances of populations. We demonstrate the utility of our approach by deriving a quantitative genetic model of diffuse coevolution mediated by exploitative competition for a continuum of resources. Other than trait and abundance distributions, this model predicts interaction networks parameterized by rates of interactions, competition coefficients, and selection gradients. We briefly investigate the relationship between selection gradients and competition coefficients. This illustrative investigation suggests selection gradients can be either positively or negatively correlated with competition coefficients depending on the ratio of interspecific trait variation to intraspecific trait variation. Hence, this approach contributes to the development of a synthetic theory of evolutionary ecology by formalizing first principle derivations of stochastic models that underlie rigorous investigations of the relationship between feedbacks of biological processes and the patterns of diversity they produce.

1 Introduction

Our goal in this manuscript is to develop a rigorous, but accessible approach to synthesize the stochastic dynamics of abundance, mean trait and heritable variation in biological populations for the study of theoretical evolutionary ecology. A primary aim of theoretical evolutionary ecology is the development of mathematical approaches to describe the evolution of populations and their interactions with both the biotic and abiotic environments in which they are embedded. Given this consideration, a natural scope for such an approach centers on quantifying the abundance dynamics of populations and the evolution of traits mediating their interactions as functions of relevant abiotic factors. Although taking into account abundance, phenotype and environment provides the basis for a partial understanding of the complex nature of biological communities, a deeper understanding must account for the effects of dispersal and the phylogeographic history of interacting lineages (Kraft et al. 2007; Hickerson et al. 2010; Manceau, Lambert, and Morlon 2016; McPeck 2017) along with the genetic basis of ecologically relevant traits (Conner 2004; Fussman, Loreau, and Abrams 2007) and feedbacks between populations and the biogeochemical cycles they ultimately depend on (Loreau 2010; Ågren and Andersson 2012). It is therefore ideal that the development of any such mathematical approach anticipates extensions to account for these important factors shaping ecological communities, especially as empirical and conceptual work in these directions continues to grow (Abdala-Roberts and Mooney 2014; Kölzsch et al. 2015; Crutsinger 2015; Fitzpatrick et al. 2015, 2017; Marx et al. 2017; Rudman et al. 2017; Skovmand et al. 2018; Nuland et al. 2019; Harmon et al. 2019). Furthermore, the approach would benefit from a stochastic component to capture the chance nature of biological reality (Lande, Engen, and Sæther 2003; Meester et al. 2018; Mubayi et al. 2019) and serve as a basis for the construction of statistical methods that measure evolutionary and ecological processes occurring in the wild. Such methods will tether theory to reality and allow for rigorous tests of hypotheses on the structure and behavior of ecological communities. In this paper we introduce a framework that establishes a formal connection between the continuous-time

dynamics of abundance and quantitative traits in stochastically evolving populations. We then demonstrate the utility of our framework through the derivation and analysis of a model of diffuse coevolution and discuss how it can be extended to account for the details mentioned above.

Current theoretical approaches to synthesize evolution and ecology have capitalized on the fact that biological fitness plays a key role in determining both sets of dynamics. While correlation of fitness and genotype is the basis of evolution by natural selection, the mean fitness across all individuals in a population determines the growth, stasis or decline of abundance. In section 2.1 we review the mathematical formalization of this connection, which has been established in the contexts of population genetics (Crow and Kimura 1970; Roughgarden 1979), evolutionary game theory (Hofbauer and Sigmund 1998; Nowak 2006; Lion 2018), quantitative genetics (Lande 1982; Doebeli 1996; Lion 2018) and a unifying framework for these three distinct approaches to evolutionary theory (Champagnat, Ferrière, and Méléard 2006) which includes our approach as a special case. We note here there are two primary differences between our aims and those of Champagnat, Ferrière, and Méléard (2006). First, instead of developing a unifying approach to evolutionary theory, we focus on developing a stochastic synthesis of population dynamics and quantitative genetics including specific expressions for the dynamics of abundance, mean trait and additive genetic variance. Second, although Champagnat, Ferrière, and Méléard (2006) provide rigorous proofs of results relevant to our approach, they do not communicate the necessary tools we make use of for deriving the dynamics of abundance, mean trait and additive genetic variance. We aim to communicate these tools to a wide audience by providing an intuitive, yet accurate treatment of white noise and associated heuristics useful for deriving new stochastic models of evolutionary ecology.

Reviewing the above accomplishments reveals a beautiful synthesis of evolution and population ecology. However, it also reveals a gap in theoretical approaches to incorporate the intrinsically random nature of populations. Specifically, in theoretical quantitative genetics the derivation of a population's response to random genetic drift is derived in discrete time under the assumption of constant effective population size using arguments based on properties of random samples (Lande 1976). Though this approach conveniently mimics the formalism provided by the Wright-Fisher model of population genetics, real population sizes fluctuate over time. Furthermore, since these fluctuations are themselves stochastic, it seems natural to derive expressions for the evolutionary response to demographic stochasticity and consider how the results relate to characterizations of random genetic drift. This can be done in continuous time for population genetic models without too much technical overhead, assuming a finite number of alleles (Lande, Engen, and Sæther 2009; Parsons, Quince, and Plotkin 2010; Gomulkiewicz, Krone, and Remien 2017). However, for populations with a continuum of types, such as a quantitative trait, finding a formal approach to derive the evolutionary response to demographic stochasticity has remained a vexing mathematical challenge. Previous work integrating stochastic processes with quantitative genetic models have profited from the simplifying assumption that phenotypic and genetic variances remain constant over time, yielding analytical approximations for the joint dynamics of abundance and the mean of a quantitative trait (Engen, Lande, and Sæther 2013). These results not only ignore the evolution genetic variance, but they focus on environmental stochasticity and assume sufficiently large populations so that demographic stochasticity is negligible. Here we account for both demographic stochasticity and the evolution of additive genetic variance by combining the calculus of white noise with results on rescaled limits of branching Brownian motion processes (BBM) and stochastic partial differential equations (SPDE), which are stochastic analogs of deterministic partial differential equations (PDE). Our goal has two components: 1) Establish a novel synthetic approach to theoretical evolutionary ecology that provides a formal connection between demographic stochasticity and random genetic drift in the context of quantitative traits. 2) Communicate some useful properties of space-time white noise, BBM and SPDE to as wide of audience as possible. With this goal in mind we will not provide a rigorous treatment of any of these deep subjects. Instead, we introduce a set of heuristics that only require the basic concepts of Riemann integration, partial differentiation and some exposure to Brownian motion and stochastic ordinary differential equations (SDE). For a concise introduction to SDE and Brownian motion, we recommend the primer by Evans (2014). Rigorous treatments of SPDE and rescaled limits of BBM can be found in Walsh (1986) and Dawson (1993) respectively.

Through accomplishing these goals this work yields five main results. Firstly, we develop a concise, but accurate approach for understanding SPDE and provide heuristics to empower mathematical evolutionary ecologists to derive novel models that relax key assumptions commonly made in combining models of evolu-

tionary and abundance dynamics. Second, we formally derive general SDE that express the joint dynamics of abundance, mean trait and additive genetic variance for populations exhibiting a wide range of potential phenotypic distributions. Third, we simplify these SDE by approximating the abundance density of phenotypes with a Gaussian curve and integrate the results with a model of imperfect inheritance to find formula that generalize classical quantitative genetic expressions. This includes an expression for additive genetic variance analogous to the expression for the response in mean phenotype found by Lande (1976). Fourth, following classical niche theory we provide a rigorous mechanistic derivation of fitness for populations experiencing resource competition and abiotic stabilizing selection using diffusion limits of measure-valued branching processes. This calculation provides a demonstration for performing such diffusion limits that can be applied in other contexts. Fifth, we explore implications of the resulting model of diffuse coevolution by investigating the relationship between selection gradients and competition coefficients.

We now summarize the basic structure of the paper. To provide motivation for the stochastic equations developed later and background for our model of coevolution, we begin with §2.1 by briefly summarizing derivations of deterministic dynamics of biological populations. Starting with a PDE (which we refer to as the Deterministic Asexual Gaussian allelic model with Abundance dynamics, abbreviated DAGA), we arrive at a general set of ordinary differential equations modelling the dynamics of abundance, trait mean and trait variance. We discuss the relationship between DAGA and previous models of phenotypic evolution that have been employed in theoretical quantitative genetics. Noting that a natural stochastic generalization of DAGA has been previously derived, we find a path to derive SDE describing the evolutionary response to demographic stochasticity. We accomplish this in §2.2 by discussing how a diffusion limit of a spatially structured branching process (i.e., a measure-valued branching process) leads to the natural SPDE appropriate for our study. We refer to this SPDE as the Stochastic Asexual Gaussian allelic model with Abundance dynamics (abbreviated SAGA). The diffusion limit in turn provides a rigorous method for constructing fitness functions used in models of evolutionary ecology. However, before we discuss measure-valued branching processes and their diffusion limits, we find it necessary to review some fundamental results on the calculus of white noise and introducing a set of mathematical tools based on these results. In §2.2 and SM §5.9 we employ these tools to derive a system of SDE generalizing our deterministic results to account for demographic stochasticity. We find that the effect of demographic stochasticity on the evolution of mean trait and phenotypic variance characterizes the process of random genetic drift in continuous time. However, although biologically insightful, these equations remain difficult to analyze and implement numerically. In §2.3 we use an assumption of normally distributed trait values to simplify these expressions into formulae that are much easier to work with. We then account for the constraint of adaptive evolution on the amount of heritable variation in a population by extending these results via a model of imperfect inheritance. The resulting equations coincide with classical results in quantitative genetics as a special case. In §3 we combine the derived equations of population dynamics with classical niche theory to formulate a model of coevolution across a guild of S species participating in exploitative competition along a common resource continuum. In SM §5.11 we apply a classical theorem on rescaled limits of BBM that allow for ecological interactions to provide a rigorous derivation. To gain biological insight, in §3.2 we numerically integrate our model of coevolution for $S = 100$ species, tracking the dynamics of traits and abundances under scenarios of weak and strong competition. We include an account of the natural history of the simulated system and discuss the significance of demographic stochasticity for structuring ecological communities. In §3.3 we provide expressions for selection gradients and competition coefficients implied by our model and use these expressions to investigate the relationship between the degree of competition and strength of coevolution. Finally, §4 concludes with a summary of accomplishments, a few remarks on the limits of this approach and future directions to incorporate more explicitly the effects of small populations, the genetic architecture of quantitative traits, feedbacks with ecosystem processes and the macroevolutionary history of interacting lineages.

2 The framework

At the core of our approach is a stochastic analog of the replicator equation with mutation in continuous time and phenotypic space (Taylor and Jonker 1978; Schuster and Sigmund 1983). From this stochastic replicator-mutator equation we derive a system of SDE for the dynamics of abundance, mean trait and

additive genetic variance of a population. Hence, our approach develops a quantitative genetic theory of evolutionary ecology. A popular alternative to quantitative genetics is the theory of adaptive dynamics. As demonstrated by Page and Nowak (2002) and Champagnat, Ferrière, and Méléard (2006), the canonical equation of adaptive dynamics can be derived from the replicator-mutator equation. Thus, one could start from the atomic roots of our approach and pursue a stochastic adaptive dynamic theory instead. We choose the former in anticipation of an extension of our approach that explicitly models the genetic details of populations.

In this section we review the derivations of the replicator-mutator equation and trait dynamics from abundance dynamics and extend these formulae along with related results to the stochastic case. The results established in this section provide the framework from which larger scale ecological structures, such as species abundance distributions and interaction networks, can be computed.

2.1 Deterministic dynamics

Our review begins by considering the dynamics of an asexually reproducing population in a homogeneous environment. For simplicity, we first assume individuals are haploid and carry one of K alleles each with a different fitness expressed as growth rate before introducing a model involving a quantitative trait. Under these assumptions, the derivation of the evolution of allele frequencies due to natural selection can be derived from expressions of exponential growth. This, and a few related approaches, have been provided by Crow and Kimura (1970, §5.3). Specifically, denoting ν_i the abundance of individuals with allele i and m_i the growth rate of allele i (called the Malthusian parameter in Crow and Kimura 1970), we have

$$\frac{d\nu_i}{dt} = m_i \nu_i. \quad (1)$$

Starting from this model, we get the total abundance of the population as $N = \sum_{i=1}^K \nu_i$, the frequency of allele i as $p_i = \nu_i/N$ and the mean fitness of the population as $\bar{m} = \sum_{i=1}^K p_i m_i$. Hence, we can employ some elementary calculus to derive the dynamics of abundance dN/dt and the dynamics of allele frequencies $dp_1/dt, \dots, dp_K/dt$ as

$$\frac{dN}{dt} = \sum_{i=1}^K \nu_i m_i = N \sum_{i=1}^K p_i m_i = \bar{m} N, \quad (2)$$

$$\frac{dp_i}{dt} = \frac{d}{dt} \frac{\nu_i}{N} = \frac{1}{N^2} \left(N \frac{d\nu_i}{dt} - \frac{dN}{dt} \nu_i \right) = \frac{1}{N} (m_i \nu_i - \bar{m} N p_i) = (m_i - \bar{m}) p_i. \quad (3)$$

Two important observations of these equations include 1) mean fitness \bar{m} determines the abundance dynamics of the entire population and 2) allele i will increase (decrease) in frequency if $m_i > \bar{m}$ ($< \bar{m}$). Equation (3) is known in the field of evolutionary game theory as the replicator equation (Hofbauer and Sigmund 1998; Nowak 2006; Lion 2018; Taylor and Jonker 1978; Schuster and Sigmund 1983). Instead of being explicitly focused on alleles, the replicator equation describes the fluctuations of relative abundances of various *types* in a population in terms of the vital rates of each type. Using a matrix of transition rates between differing types, it is straight-forward to extend the replicator equation to include mutation, which is known as the replicator-mutator equation (Nowak 2006).

Inspired by equations (1)-(3), we derive an analog of the replicator-mutator equation for a continuum of types (that is, for a quantitative trait). In particular, we model a continuously reproducing population with trait values $x \in \mathbb{R}$ and an abundance density $\nu(x, t)$ that represents the amount of individuals in the population with trait value x at time t . Hence, the abundance density satisfies $N(t) = \int_{-\infty}^{+\infty} \nu(x, t) dx$ and $p(x, t) = \nu(x, t)/N(t)$ is the relative density of trait x which we also refer to as the phenotypic distribution.

To stay within the realm of biological plausibility we require a set technical assumptions. First, we assume the initial abundance density is continuous, non-negative, integrable and has finite trait mean and variance. That is, we assume $\nu(x, 0)$ is continuous in x , satisfies $\nu(x, 0) \geq 0$ for all $x \in \mathbb{R}$ and

$$N(0) = \int_{-\infty}^{+\infty} \nu(x, 0) dx < +\infty, \quad (4)$$

$$-\infty < \bar{x}(0) = \int_{-\infty}^{+\infty} xp(x,0)dx < +\infty, \quad (5)$$

$$\sigma^2(0) = \int_{-\infty}^{+\infty} (x - \bar{x}(0))^2 p(x,0)dx < +\infty, \quad (6)$$

where $\bar{x}(t)$ and $\sigma^2(t)$ are respectively the mean trait and phenotypic variance at time $t \geq 0$. Second, we assume selection is determined by the growth rate $m(h, x)$ that is differentiable with respect to both arguments and is bounded above by some $r \in \mathbb{R}$ for all $x \in \mathbb{R}$ and $h \geq 0$. We denote by K an operator that takes functions such as $\nu(x, t)$ as its argument and returns other functions that may still depend on the spatial variable x and the temporal variable t . For our application we will be focused on operators K that can be written as $(K\nu)(x, t) = \int_{-\infty}^{+\infty} \kappa(x - y)\nu(y, t)dy$ for some non-negative and bounded function κ . We set $h = (K\nu)(x, t)$ to account for nonlocal effects of the abundance density $\nu(x, t)$ on the fitness of individuals with trait value x (Volpert 2014). An example of a nonlocal effect comes from competition for a common resource among all individuals in a population regardless of their trait value. In this case all individuals in the population effect each others fitness' even though they may exhibit diverse trait values. The term nonlocal comes from interpreting the trait value as spatial location. From here on we abbreviate $m(h, x) = m((K\nu)(x, t), x)$ to just $m(\nu, x)$. Third, we assume mutation is captured by diffusion with coefficient $\frac{\mu}{2}$. With these technicalities addressed we model the demographic dynamics of a population and the dynamics of a quantitative character simultaneously by the PDE

$$\frac{\partial}{\partial t}\nu(x, t) = m(\nu, x)\nu(x, t) + \frac{\mu}{2}\frac{\partial^2}{\partial x^2}\nu(x, t) \quad (7)$$

with the initial condition $\nu(x, 0)$ described above. This PDE is semilinear due to the dependency of the growth rate $m(\nu, x)$ on the solution $\nu(x, t)$ and is referred to as a scalar reaction-diffusion equation (Henry 1981; Evans 2010). Interpreting the trait value x as spatial location and ignoring nonlocal effects, which can be satisfied by setting $K\nu = \nu$, this model of spatially distributed population dynamics has been intensely studied (for a review, see Cantrell and Cosner 2004). When $\mu = 0$, equation (7) can be seen as an analog of equation (1) for a continuum of types. By assuming mutation acts as diffusion, the effect of mutation causes $\nu(x, t)$ to flatten out over time. In fact, if the growth rate is constant across x , then this model of mutation will cause $\nu(x, t)$ to converge to a flat line as $t \rightarrow \infty$. Although clearly an idealized representation of biological reality, this model is sufficiently general to capture a large class of dynamics including density dependent growth and frequency dependent selection. As an example, logistic growth combined with quadratic stabilizing selection can be captured using the growth rate

$$m(\nu, x) = r - \frac{a}{2}(\theta - x)^2 - c \int_{-\infty}^{+\infty} \nu(y, t)dy \quad (8)$$

where $r \in \mathbb{R}$ is the intrinsic growth rate in the absence of abiotic stabilizing selection, $a > 0$ is the strength of abiotic stabilizing selection around the phenotypic optimum $\theta \in \mathbb{R}$, $c > 0$ captures the sensitivity of fitness to intraspecific competition and we have set $\kappa(x - y) = 1$ so that competitive interactions cause the same reduction in fitness regardless of trait value. This exemplary fitness function has a few convenient properties that we briefly take note of. First, the effect of competition induces a local carrying capacity on the population, leading to a finite equilibrium abundance over bounded subsets of \mathbb{R} . Second, abiotic selection prevents the abundance density from diffusing too far from the abiotic optimum, leading to a finite equilibrial abundance across all of \mathbb{R} , $\lim_{t \rightarrow \infty} N(t) = \frac{1}{c}(r - \frac{1}{2}\sqrt{a\mu})$, finite equilibrial mean trait $\lim_{t \rightarrow \infty} \bar{x}(t) = \theta$ and finite equilibrial phenotypic variance $\lim_{t \rightarrow \infty} \sigma^2(t) = \frac{\sqrt{\mu}}{a}$, so long as $\bar{x}(0) \in \mathbb{R}$, $\sigma^2(0) \in [0, +\infty)$, $N(0) \in (0, +\infty)$ and $r > \frac{1}{2}\sqrt{a\mu} > 0$. We prove these statements in SM §5.4. Note in particular the coincidence of equilibrial phenotypic variance predicted by this model and that predicted by the classic Gaussian allelic model of quantitative genetics (Lande 1975; Bürger 2000; Johnson and Barton 2005). By replacing $\kappa(x - y) = 1$ in expression (8) with a particular Gaussian function, we will find in §3 and SM §5.11 this fitness function becomes equivalent to a fitness function derived from niche theory that we use to model coevolution driven by resource competition.

228 To derive a replicator-mutator equation from equation (7), we employ the chain rule from calculus. Writing
 229 $\bar{m}(t) = \int_{-\infty}^{+\infty} m(\nu, x)p(x, t)dx$ for the mean fitness, we have

$$\begin{aligned} \frac{d}{dt}N(t) &= \frac{d}{dt} \int_{-\infty}^{+\infty} \nu(x, t)dx = \int_{-\infty}^{+\infty} \frac{\partial}{\partial t} \nu(x, t)dx \\ &= \int_{-\infty}^{+\infty} m(\nu, x)\nu(x, t)dx + \int_{-\infty}^{+\infty} \frac{\mu}{2} \frac{\partial^2}{\partial x^2} \nu(x, t)dx \\ &= N(t) \int_{-\infty}^{+\infty} m(\nu, x)p(x, t)dx = \bar{m}(t)N(t). \end{aligned} \quad (9)$$

230 Using our assumptions on mutation and rate of growth, we show in SM §5.2 $\nu(x, t)$ is twice differentiable
 231 with respect to x and $\int_{-\infty}^{+\infty} \nu(x, t)dx < \infty$ for all $t \geq 0$. This implies that we are justified in swapping
 232 the order of differentiation and integration and the result $\int_{-\infty}^{+\infty} \frac{\partial^2}{\partial x^2} \nu(x, t)dx = 0$ can be derived from the
 233 fundamental theorem of calculus. Biological reasoning agrees with this latter result since mutation neither
 234 creates nor destroys individuals, but merely changes their type from their parental type. Taking the same
 235 approach, we derive the dynamics of the phenotypic distribution $p(x, t)$ in response to selection and mutation
 236 as

$$\begin{aligned} \frac{\partial}{\partial t}p(x, t) &= \frac{\partial}{\partial t} \frac{\nu(x, t)}{N(t)} = \frac{1}{N^2(t)} \left(N(t) \frac{\partial}{\partial t} \nu(x, t) - \nu(x, t) \frac{d}{dt} N(t) \right) \\ &= \frac{1}{N(t)} \left(m(\nu, x)\nu(x, t) + \frac{\mu}{2} \frac{\partial^2}{\partial x^2} \nu(x, t) - \bar{m}(t)\nu(x, t) \right) \\ &= (m(\nu, x) - \bar{m}(t))p(x, t) + \frac{\mu}{2} \frac{\partial^2}{\partial x^2} p(x, t). \end{aligned} \quad (10)$$

237 This result closely resembles Kimura’s continuum-of-alleles model (Kimura 1965; Bürger 1986). The primary
 238 difference being that our model utilizes diffusion instead of convolution with an arbitrary mutation kernel. Of
 239 course, our model of mutation can be derived as an approximation to Kimura’s model, which, for sexually
 240 reproducing populations, has been referred to as the Gaussian allelic approximation in reference to the
 241 distribution of mutational effects at loci in a genome on the values of traits (Lande 1975; but see also Bürger
 242 2000; and Johnson and Barton 2005), the infinitesimal model in reference to modelling continuous traits as
 243 being encoded by an infinite number of loci each having infinitesimal effect (Barton, Etheridge, and Véber
 244 2017) and the Gaussian descendants approximation in reference to offspring trait values being normally
 245 distributed around their parental values (Turelli 2017). Alternatively, since diffusion is the continuous-time
 246 equivalent to convolution against a Gaussian kernel (SM §5.3), equation (10) can also be seen as a special
 247 case of Kimura’s continuum-of-alleles model. We return to these concepts in §2.3.2 where we review a simple
 248 model of inheritance that leads us to an expression for the stochastic evolution of additive genetic variance.
 249 To clarify the distinction between this model and previous models of phenotypic evolution we refer to the
 250 PDE (7) from which (10) was derived as the Deterministic Asexual Gaussian allelic model with Abundance
 251 dynamics (abbreviated DAGA). Later, we will extend this model to include the effects of demographic
 252 stochasticity, which we refer to as the Stochastic Asexual Gaussian allelic model with Abundance dynamics
 253 (abbreviated SAGA).

254 The covariance of fitness and phenotype across the population is defined as

$$\text{Cov}_t(m(\nu, x), x) = \int_{-\infty}^{+\infty} (m(\nu, x) - \bar{m}(t))(x - \bar{x}(t))p(x, t)dx. \quad (11)$$

255 Hence, the dynamics of the mean trait $\bar{x}(t)$ can be derived as

$$\begin{aligned}\frac{d}{dt}\bar{x}(t) &= \frac{d}{dt} \int_{-\infty}^{+\infty} xp(x,t)dx = \int_{-\infty}^{+\infty} x \frac{\partial}{\partial t} p(x,t)dx \\ &= \int_{-\infty}^{+\infty} x(m(\nu, x) - \bar{m}(t))p(x,t) + x \frac{\mu}{2} \frac{\partial^2}{\partial x^2} p(x,t)dx = \text{Cov}_t(m(\nu, x), x). \quad (12)\end{aligned}$$

Equation (12) is a continuous time analog of the well known Robertson-Price equation without transmission bias (Robertson 1966; Price 1970; Frank 2012; Queller 2017; Lion 2018). Whether or not the covariance of fitness and phenotype creates change in \bar{x} to maximize mean fitness \bar{m} depends on the degree to which selection is frequency dependent (Lande 1976). Since this change is driven by a covariance with respect to phenotypic diversity, the response in mean trait to selection is mediated by the phenotypic variance. In particular, when $\sigma^2 = 0$, \bar{x} will not respond to selection. The result $\int_{-\infty}^{+\infty} x \frac{\partial^2}{\partial x^2} p(x,t)dx = 0$ can be found by applying integration by parts. Following the approach taken to calculate the evolution of \bar{x} , we find the response of phenotypic variation to this model of selection and mutation is

$$\frac{d}{dt}\sigma^2(t) = \text{Cov}_t(m(\nu, x), (x - \bar{x})^2) + \mu. \quad (13)$$

For the sake of space we relegate the derivation of $d\sigma^2/dt$ to SM §5.5. In the absence of mutation equation (13) agrees with the result derived by Lion (2018) for discrete phenotypes. From a statistical perspective, if we think of $(x - \bar{x})^2$ as a square error, then in analogy to the dynamics of the mean trait, we see that the response in σ^2 to selection can be expressed as a covariance of fitness and square error, which is defined in analogy to $\text{Cov}_t(m(\nu, x), x)$. Just as for the evolution of $\bar{x}(t)$, this covariance also creates change in σ^2 that can either increase or decrease mean fitness \bar{m} , depending on whether or not individual fitness depends on the distribution of traits across the entire population. The effect of selection on phenotypic variance can be positive or negative depending on whether selection is stabilizing or disruptive.

In SM §5.9, we extend these results to include the effects of demographic stochasticity. The key realization in this direction is that a rigorous derivation of a SPDE that naturally generalizes DAGA and accounts for ecological interactions has been provided by Li (1998). To understand how this SPDE was derived, we provide an informal discussion of measure-valued branching processes (which treat populations as sets of discrete individuals) and their diffusion limits, the so-called superprocesses (which treat population size as a continuously varying number). Similar to the approach taken by Champagnat, Ferrière and Méléard (2006), we begin with a BBM that models populations as discrete sets of reproducing individuals whose vital rates depend on their trait value as well as the state of the entire population. Taking a large population size limit and keeping our assumption of single dimensional traits, we employ a pair of classical results that show, under the appropriate rescaling in time, phenotypic space and population density, a sequence of rescaled BBM converges to a limiting process that can be characterized by a SPDE (Méléard and Roelly 1993; Li 1998). The limiting processes of rescaled BBM have been referred to as measure-valued Markov processes (Dawson 1993) or superprocesses (Etheridge 2000). Under the simplifying assumptions inherited from our treatment of deterministic dynamics and the additional assumption that the magnitude of demographic stochasticity is independent of trait values, we obtain as a special case a relatively simple expression for an SPDE that generalizes DAGA. The simplicity of our special case allows us to use properties of space-time white noise processes to derive a set of SDE that generalize equations (9), (12) and (13) to include the effects of demographic stochasticity. Classical expressions for the effects of random genetic drift on the evolution of mean traits are obtained as a special case.

In the following section we provide the necessary mathematical tools needed to derive SDE from SPDE. Since our aim is to present this material to as wide of audience as possible, our approach deviates from standard definitions to remove the need for a detailed technical treatment. In addition to the notions of Riemann integration and partial differentiation already employed, the reader will only need some elementary probability and an intuitive understanding of SDE, including Brownian motion. Because space-time white noise, denoted by $\dot{W}(x, t)$, appears in the SPDE characterizing diffusion limits of BBM, we begin by defining $\dot{W}(x, t)$ and illustrating its relevant properties including a set of heuristics for performing calculations.

Treating only the simplest of cases, we then provide a brief review of BBM, their diffusion limits and the SPDE that characterize them. For those not interested in the white noise calculus or superprocesses and would rather jump straight into more biologically relevant results, we recommend skipping to §2.3.

2.2 White noise calculus and superprocesses

2.2.1 Introduction to white noise

One can think of white noise as the static seen on old television sets or infinitely detailed random dust spread across both time and space. From a more mathematical, yet still informal perspective, white noise can be thought of as a stochastic process. That is, we can picture white noise as a collection of random variables indexed by time and possibly space. In relation to Brownian motion, denoted by W , white noise can be interpreted of as the derivative of Brownian motion with respect to time, denoted \dot{W} . Since Brownian motion can be thought to take infinitesimally small Gaussian distributed jumps at each time point, this leads to the conceptualization of white noise as a collection of Gaussian distributed random variables. Figure 1 illustrates realizations of this conceptualized white noise in one (left) and two (right) dimensions.

Figure 1: Approximations of sample paths of temporal white noise (left) and space-time white noise (right) with brightness scaled to value.

However, it turns out that realizations of white noise do not exist as functions in the classical sense. Indeed, since Brownian motion is nowhere differentiable with respect to time, white noise cannot be formally understood as a time derivative. Thus our notation \dot{W} is only meant to aid intuition and not be taken as formal. A formal understanding is possible by considering white noise as a *measure*-valued process (Dawson 1975; Walsh 1986) or as a *generalized* process that acts on classically defined functions or stochastic processes to return either random variables or stochastic processes (Krylov and Rozovskii 1981; Da Prato and Zabczyk 2014). Since a measure-valued process can be defined from a generalized process and a generalized process can be defined from a measure-valued process, the distinction between the two is more or less a matter of perspective. However, we find the perspective of white-noise as a generalized process to be a more efficient route for developing heuristics to help with some routine calculations involved with deriving SDE from SPDE. Hence, the notion of a generalized process provides the general idea implemented here. Although the treatments of SPDE provided by Krylov and Rozovskii (1981) and Da Prato and Zabczyk (2014) extend the theory of SDE to formally treat SPDE in a general and elegant fashion, they require the navigation of an enormous amount of technical definitions and detailed proofs. To extract some particularly useful results from this theory relevant to our goal of synthesizing the stochastic dynamics of biological populations, we provide a streamlined approach by capitalizing on the solid ground these authors have established. For instance, instead of rigorously proving properties of white-noise, we simply define them to be so, taking solice

in the fact that the technical details have been worked out elsewhere. In SM §5.7 we show how our informal treatment is related to the rigorous treatment provided by Da Prato and Zabczyk (2014).

Before diving in, we shed a bit of light on the idea of a generalized process. A generalized process is the stochastic analog of a generalized function, such as the Dirac delta function δ . Often one sees δ defined as a function satisfying the properties $\delta(x) = 0$ for $x \neq 0$ and $\int_{-\infty}^{+\infty} \delta(x)dx = 1$. However, since there is no function that satisfies these properties, we refer to δ as a generalized function. An alternative definition of δ considers its action on classically defined functions f . In particular, $\delta(f) = f(0)$, which can be heuristically written as $\int_{-\infty}^{+\infty} f(x)\delta(x)dx = f(0)$. Similarly, other generalized functions can be defined by their action on classically defined functions. Then, just as a generalized function operates on classical functions to return a value, a generalized process acts on a set of functions (or processes) to return a random variable (or a classically defined stochastic process). For a brief primer on the theory of generalized functions, see the addendum to chapter 3 of Kolmogorov and Fomin (1999).

2.2.2 Definition and basic properties of white noise

Throughout this section, we minimize notation by writing $\int_{\mathbb{R}} f(x)dx = \int_{-\infty}^{+\infty} f(x)dx$ and similarly $\int_D f(x)dx$ for the integral of f over $D \subset \mathbb{R}$. We define \mathcal{N}_2 as the set of stochastic processes $f(x, t)$ that are continuous in t and satisfy $\mathbb{E} \left(\int_0^t \int_{\mathbb{R}} f^2(x, s)dxds \right) < +\infty$ for each $t \geq 0$. The operator \mathbb{E} denotes expectation with respect to the underlying probability space. For each $t \geq 0$ we set

$$\|f\|_t = \sqrt{\mathbb{E} \left(\int_0^t \int_{\mathbb{R}} f^2(x, s)dxds \right)}, \quad (14)$$

and make use of the convention $f = g$ if $\|f - g\|_t = 0$ for all $t \geq 0$. Later, when we investigate stochastic dynamics of the abundance density $\nu(x, t)$, we will find $\sqrt{\nu} \in \mathcal{N}_2$. This enables us to utilize the heuristics developed in this section for the derivation of SDE describing the stochastic dynamics of $N(t)$, $\bar{x}(t)$ and $\sigma^2(t)$.

We define a generalized stochastic process \mathbf{W} that maps processes $f \in \mathcal{N}_2$ to real-valued stochastic processes indexed by time $t \geq 0$, but not by space. To evaluate \mathbf{W} for a process $f \in \mathcal{N}_2$ and some time $t \geq 0$ we write $\mathbf{W}_t(f)$. Specifically, for any $f, g \in \mathcal{N}_2$, we define $\mathbf{W}(f)$ and $\mathbf{W}(g)$ to be Gaussian processes satisfying, for any $t, t_1, t_2 \geq 0$,

$$\mathbb{E}(\mathbf{W}_t(f)) = \mathbb{E}(\mathbf{W}_t(g)) = 0, \quad (15)$$

$$\mathbb{C}(\mathbf{W}_{t_1}(f), \mathbf{W}_{t_2}(g)) = \mathbb{E} \left(\int_0^{t_1 \wedge t_2} \int_{\mathbb{R}} f(x, s)g(x, s)dxds \right), \quad (16)$$

where $t_1 \wedge t_2 = \min(t_1, t_2)$ and \mathbb{C} denotes covariance with respect to the underlying probability space. In particular, denoting \mathbb{V} the variance operator with respect to the underlying probability space, we have $\mathbb{V}(\mathbf{W}_t(f)) = \|f\|_t^2$ for all $t \geq 0$ and $f \in \mathcal{N}_2$. The operators \mathbb{E} and \mathbb{C} are to be distinguished from $\bar{f}(t)$ and $\text{Cov}_t(f, g)$ which denote expectation and covariance with respect to phenotypic diversity at time $t \geq 0$.

Since Gaussian processes are characterized by their expectations and covariances and since we assume the \mathcal{N}_2 processes are continuous in time, the processes $\mathbf{W}(f)$ and $\mathbf{W}(g)$ are well defined. As an example, if $f \in \mathcal{N}_2$ is independent of time, then $\mathbf{W}(f)$ is a Brownian motion with variance at time $t \geq 0$ equal to $\|f\|_t^2 = t \mathbb{E}(\int_{\mathbb{R}} f^2(x, 0)dx)$. With the generalized process \mathbf{W} defined, we define the space-time white noise $\dot{W}(x, t)$ implicitly via the stochastic integral

$$“ \int_0^t \int_{\mathbb{R}} f(x, s)\dot{W}(x, s)dxds ” = \mathbf{W}_t(f), \quad \forall f \in \mathcal{N}_2, \quad t \geq 0. \quad (17)$$

We place quotations in the above expression to emphasize its informal nature and that it should not be confused with classical Riemann integration. Following this definition of white noise, we compute its value

by sampling it using \mathcal{N}_2 processes. For example, integrating white noise over a region $D \times [0, t]$, with $t > 0$ and D a bounded subset of \mathbb{R} , is equivalent to evaluating $\mathbf{W}_t(I_{D \times [0, +\infty)})$ for the deterministic process

$$I_{D \times [0, +\infty)}(x, t) = \begin{cases} 0, & x \notin D \\ 1, & x \in D \end{cases}. \quad (18)$$

Since

$$\|I_{D \times [0, +\infty)}\|_t^2 = \mathbb{E} \left(\int_0^t \int_{\mathbb{R}} I_{D \times [0, +\infty)}^2(x, s) dx ds \right) = t \int_D dx = t|D| < +\infty, \quad (19)$$

where $|D|$ denotes the length of D , we have $I_{D \times [0, +\infty)} \in \mathcal{N}_2$. Thus, using equations (15) and (16) and adopting the informal notation introduced in equation (17), we can write the following

$$\mathbb{E} \left(\int_0^t \int_D \dot{W}(x, s) dx ds \right) = 0, \quad (20)$$

$$\mathbb{V} \left(\int_0^t \int_D \dot{W}(x, s) dx ds \right) = t|D|. \quad (21)$$

Using this informal notation, equations (15) and (16) can be rewritten as

$$\mathbb{E} \left(\int_0^t \int_{\mathbb{R}} f(x, s) \dot{W}(x, s) dx ds \right) = 0, \quad (22)$$

$$\mathbb{C} \left(\int_0^{t_1} \int_{\mathbb{R}} f(x, s) \dot{W}(x, s) dx ds, \int_0^{t_2} \int_{\mathbb{R}} g(x, s) \dot{W}(x, s) dx ds \right) = \int_0^{t_1 \wedge t_2} \int_{\mathbb{R}} f(x, s) g(x, s) dx ds. \quad (23)$$

To relate these formulae to the common notation used for SDE, we write

$$\hat{f}(x, t) = \frac{f(x, t)}{\sqrt{\int_{\mathbb{R}} f^2(y, t) dy}} \quad \text{and} \quad d\hat{\mathbf{W}}_t(f) = \left(\int_{\mathbb{R}} \hat{f}(x, t) \dot{W}(x, t) dx \right) dt \quad (24)$$

so that

$$\int_0^t d\hat{\mathbf{W}}_s(f) = \int_0^t \int_{\mathbb{R}} \frac{f(x, s)}{\sqrt{\int_{\mathbb{R}} f^2(s, y) dy}} \dot{W}(x, s) dx ds. \quad (25)$$

This implies

$$\mathbb{E} \left(\int_0^t d\hat{\mathbf{W}}_s(f) \right) = 0, \quad \mathbb{C} \left(\int_0^{t_1} d\hat{\mathbf{W}}_s(f), \int_0^{t_2} d\hat{\mathbf{W}}_s(f) \right) = t_1 \wedge t_2 \quad (26)$$

and in particular, as a function of t , $\int_0^t d\hat{\mathbf{W}}_s(f)$ is a standard Brownian motion for any $f \in \mathcal{N}_2$. Hence, $d\hat{\mathbf{W}}_t(f)$ is analogous to the traditional shorthand used to denote stochastic differentials. Thus, equation (23) effectively extends Itô's multiplication table to:

Table 1: An extension of Itô's multiplication table.

	$d\hat{\mathbf{W}}_t(f)$	$d\hat{\mathbf{W}}_t(g)$	dt
$d\hat{\mathbf{W}}_t(f)$	dt	$\left(\int_{\mathbb{R}} \hat{f}(x, t) \hat{g}(x, t) dx \right) dt$	0
$d\hat{\mathbf{W}}_t(g)$	$\left(\int_{\mathbb{R}} \hat{f}(x, t) \hat{g}(x, t) dx \right) dt$	dt	0
dt	0	0	0

The extension of Itô's multiplication table and properties of white noise outlined in this subsection provide a useful set of tools for working with SPDE. In SM §5.9 we employ these tools to derive SDE that track the dynamics of abundance, mean trait and phenotypic variance of a population from a particular SPDE. In the following subsection, we review how this particular SPDE naturally arises as the diffusion limit of a BBM.

2.2.3 From branching processes to SPDE

In real populations individuals are born and potentially reproduce before they ultimately die. These three events provide the basic ingredients of a branching process. Mathematical investigations of such processes have a relatively deep history (Kendall 1966). The most simple branching process, known as the Galton-Watson process, describes the number of individuals alive at a given time $t \geq 0$ as a non-negative integer (Kimmel and Axelrod 2015). Feller (1951) introduced a formal method to approximate branching processes with diffusion processes which are continuous in state (i.e., population size is approximated as a continuous quantity). Since diffusion processes possess greater analytical tractability than branching processes, Feller's method, known as the diffusion limit, has acquired immense popularity particularly in the field of mathematical population genetics (Ewens 2004). For over the past half of a century a great deal of accomplishments have been achieved in formalizing the diffusion limits of branching processes that describe populations of individuals occurring in some continuous space (Watanabe 1968; Dawson 1975, 1978; Perkins 1992, 1995; Méléard and Roelly 1993; Li 1998; Bertoin and Le Gall 2003; Etheridge 2008; Barton and Etheridge 2019). This space can represent geographic space or, relevant to our context, phenotypic space. In the following subsection, we describe the BBM process, which is a particularly important branching process with spatial structure. This process has been very useful in the study of SPDE due to its simplifying assumption that individuals do not interact. However, this assumption imposes an unfortunate restriction by precluding the modelling of ecological interactions. We therefore follow our discussion of BBM with a review of a few important results on spatially structured branching processes that account for interactions.

Branching Brownian motion

A BBM tracks individuals navigating d -dimensional Euclidean space that reproduce and senesce between exponentially distributed intervals. Unlike other stochastic processes that take values in \mathbb{R}^d , BBM takes values in the set of *non-negative finite measures* over \mathbb{R}^d . Intuitively, one can think of a finite measure as a function that maps subsets of \mathbb{R}^d to real numbers. To be formal, we only consider the Borel subsets of \mathbb{R}^d corresponding to the Euclidean metric, but understanding this technicality is not crucial to our discussion. In particular, denoting X_t a BBM, for a subset $D \subset \mathbb{R}^d$, $X_t(D)$ returns the (random) number of individuals alive within the region D at time $t \geq 0$. The BBM has three main components:

- 1) **Branching rate:** In our formulation of BBM we assume Lifetimes of individuals are exponentially distributed with death rate $\lambda > 0$ and reproduction occurs simultaneously with death. Biologically, this implies individuals are semelparous. An alternative formulation treats birth and death events separately to model iteroparity. However, under the appropriate rescaling, both approaches converge to the same diffusion limit. We therefore choose the former approach for the sake of simplicity.
- 2) **Reproductive law:** When a birth event occurs a random (possibly zero) number of offspring are left. The distribution of offspring left is called the reproductive law or branching mechanism. We denote the mean and variance in reproductive output by \mathscr{W} and V respectively. The case of $\mathscr{W} = 1$ is referred to as the critical condition. Under the critical condition the probability that extinction occurs in finite time is equal to one.
- 3) **Spatial movement:** Each offspring is born at the current location of their parent. Immediately after birth they move around space according to d -dimensional Brownian motion with diffusion parameter $\sqrt{\mu}$. In our context we interpret spatial movement as mutation so that the location of an individual at death represents the value of its phenotype. Then an individual born at location $x \in \mathbb{R}^d$ that lives for $\tau > 0$ units of time will have a normally distributed trait centered on x with covariance matrix equal to $\tau\mu$ times the $d \times d$ identity matrix. Hence, offspring inherit normally distributed traits centered on their parental trait. This fact creates a vital link to the deterministic dynamics reviewed above. Indeed, in the absence of selection, the deterministic PDE (7) reduces to the $d = 1$ -dimensional Kolmogorov forward equation for a Brownian motion with diffusion parameter $\sqrt{\mu}$.

To obtain a SPDE from a BBM we take a diffusion limit. There are several ways to do this, but a simple approach is to rescale the mass of individuals and time by $1/n$, diffusion by $\mu \rightarrow \mu/n$, branching rate by

431 $\lambda \rightarrow n\lambda$, fitness by $\mathcal{W} \rightarrow \mathcal{W}^{1/n}$ and consider the limit as $n \rightarrow \infty$. Denoting the rescaled process by $X_t^{(n)}(D)$,
 432 the limiting process $\mathcal{X}_t = \lim_{n \rightarrow \infty} X_t^{(n)}$ is called a super-Brownian motion and is also a non-negative finite
 433 measure-valued process (Watanabe 1968). However, instead of returning the number of individuals alive in a
 434 region of space, super-Brownian motion returns the *mass* of the population concentrated in a region of space.
 435 Since we have rescaled individual mass by $1/n$ and took the limit $n \rightarrow \infty$, individuals are no longer discrete
 436 units. Instead, the particle view of the population gets replaced by a blob spread across d -dimensional space.
 437 In particular, the value of $\mathcal{X}_t(D)$ is a continuously varying non-negative random variable for any $t \geq 0$ and
 438 $D \subset \mathbb{R}^d$.

439 Unfortunately, just as with cream cheese spread across too much toast, the blob perspective of the population
 440 may exhibit some complicated spatial discontinuities. However, for spatial dimension $d = 1$, it turns out
 441 that \mathcal{X}_t is absolutely continuous with respect to the Lebesgue measure for each $t \geq 0$ (Konno and Shiga
 442 1988; Reimers 1989). This means that we can write $\mathcal{X}_t(D) = \int_D \nu(x, t) dx$ for some density process $\nu(x, t)$.
 443 Setting $\lambda = 1$ and $m = \ln \mathcal{W}$ this density process satisfies the SPDE

$$\frac{\partial}{\partial t} \nu(x, t) = m\nu(x, t) + \frac{\mu}{2} \frac{\partial^2}{\partial x^2} \nu(x, t) + \sqrt{V\nu(x, t)} \dot{W}(x, t). \quad (27)$$

444 Since $\nu(x, t)$ is not generally differentiable in x or t , the derivatives in expression (27) are taken in the *weak*
 445 sense (for examples, see Evans 2010). That is, to rigorously interpret SPDE (27), we integrate the solution
 446 $\nu(x, t)$ against functions $f \in C_b^2(\mathbb{R})$, where $C_b^2(\mathbb{R})$ is the set of bounded and twice continuously differentiable
 447 functions on \mathbb{R} . Hence, equation (27) is just an abbreviation for

$$\begin{aligned} \int_{\mathbb{R}} \nu(x, t) f(x) dx - \int_{\mathbb{R}} \nu(x, 0) f(x) dx &= \int_0^t \int_{\mathbb{R}} \nu(x, s) \left(m f(x) + \frac{\mu}{2} \frac{\partial^2}{\partial x^2} f(x) \right) ds dx \\ &+ \int_0^t \int_{\mathbb{R}} f(x) \sqrt{V\nu(x, s)} \dot{W}(x, s) dx ds, \quad \forall f \in C_b^2(\mathbb{R}). \end{aligned} \quad (28)$$

448 This expression is referred to as the *mild* solution of (27). For more on the general theory of SPDE see
 449 Walsh (1986) and Da Prato and Zabczyk (2014). Note that since $\nu(x, t)$ is the density of a finite measure,
 450 it is integrable for each $t \geq 0$. Thus, since for some $M > 0$, $|f(x)| \leq M$ for every $x \in \mathbb{R}$, setting $\varphi(x, t) =$
 451 $f(x) \sqrt{V\nu(x, t)}$ implies $\varphi \in \mathcal{N}_2$. Hence, the white noise integral on the right-hand side of equation (28)
 452 can be understood using the heuristics introduced above. Evaluating equation (28) in the particular case of
 453 $f(x) \equiv 1$ returns the total mass process, which we refer to as the total abundance $N(t)$.

454 A convergence theorem for the diffusion limit of a generalization of BBM was established by Watanabe
 455 (1968). Dawson (1975) suggested that, for spatial dimension $d = 1$, this diffusion limit should admit a density
 456 process that satisfies a SPDE. Konna and Shiga (1988) and Reimers (1989) independently proved Dawson's
 457 suggestion was indeed correct. The diffusion limit of this more general branching process (in arbitrary spatial
 458 dimension) is referred to as a Dawson-Watanabe superprocess (Etheridge 2000). Conditioning a Dawson-
 459 Watanabe superprocess to have constant mass returns a Fleming-Viot process (Etheridge and March 1991;
 460 Perkins 1991) which has been popular in studies of spatial population genetics. In particular, an extension
 461 of the Fleming-Viot process, known as the Λ -Fleming-Viot process, was introduced by Bertoin and Le Gall
 462 (2003) and coined by Etheridge (2008) where it was used to resolve some technical challenges in modelling
 463 isolation by distance (Felsenstein 1975; see also Barton, Etheridge, and Véber 2013; and Barton and Etheridge
 464 2019). Although this provides an impressive list of accomplishments, the Dawson-Watanabe superprocess
 465 falls short of our needs. In particular this process assumes individuals do not interact and thus precludes
 466 its ability to model nonlocal effects on the fitness of individuals, such as those produced via ecological
 467 interactions. However, this concern has been addressed, leading to constructions of superprocesses that
 468 account for interactions among individuals. In the next subsection we summarize the main results in this
 469 area and introduce the SPDE that provides the basis for our approach to theoretical evolutionary ecology.

470 Interacting superprocesses

471 In the above subsection we reviewed the diffusion limit of an especially tractable measure-valued branching
 472 process. However, we found the simplicity of this process restricts us from modelling nonlocal effects on

the fitness of individuals. Here, we discuss superprocesses that account for such effects. The existence of diffusion limits for a class of measure-valued branching processes involving nonlocal effects has been treated by Méléard and Roelly (1992, 1993). The interactions can manifest as dependencies of the spatial movement or reproductive law of individuals on their position x and the state of the whole population described by X_t . An important result of Méléard and Roelly (1992, 1993) is a theorem that provides sufficient conditions to construct a sequence of rescaled measure-valued branching processes that converge to a generalization of the Dawson-Watanabe superprocess that includes interactions. The rescaling is analogous to that described above for non-interacting Dawson-Watanabe superprocesses, but now the reproductive law described by $\mathcal{W}(X_t, x)$ and $V(X_t, x)$, branching rate $\lambda(X_t, x)$ and diffusion parameter $\sqrt{\mu(X_t, x)}$ are allowed to depend on the whole population X_t and individual location x . In Figure 2 we demonstrate this rescaling in discrete time for a population experiencing stabilizing selection and logistic growth. Since time is discretized, the process we simulate is formally a branching random walk. For further details on our simulation see SM §5.8.

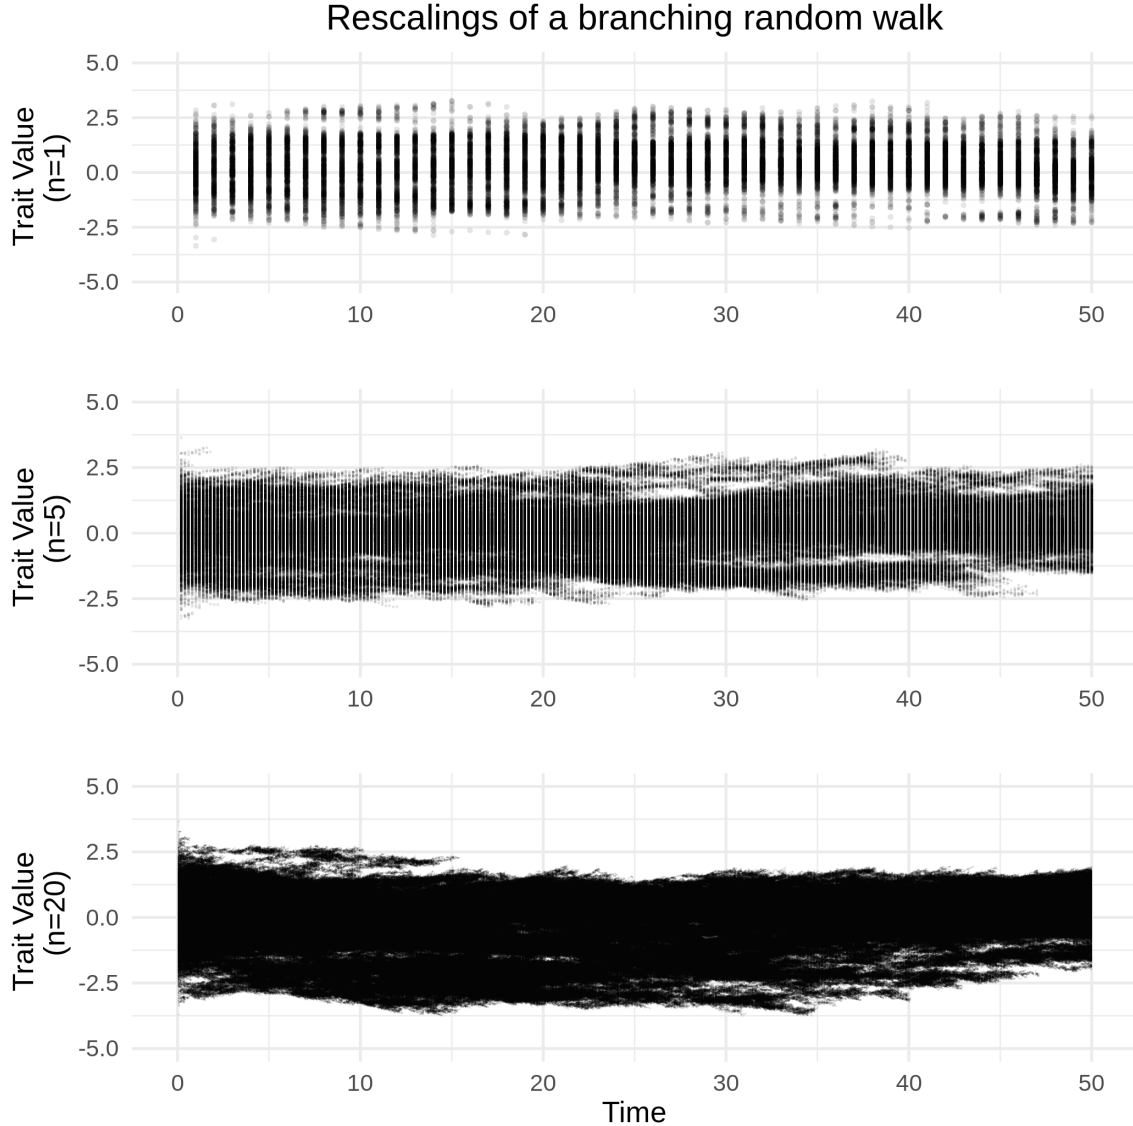

Figure 2: Rescaled sample paths of a branching random walk under stabilizing selection and logistic growth. The top plot displays a sample path without scaling ($n = 1$), the middle plot shows a sample path rescaled by $n = 5$ and the bottom plot shows a sample path rescaled by $n = 20$.

Interactions that manifest in the spatial movement can be used to model mutation bias and those manifesting in the reproductive law can model density-dependent growth rates and frequency-dependent selection. Perkins (1992, 1995) developed a theory of stochastic integration with respect to the so-called *Brownian trees* to characterize interacting superprocesses and establish properties of existence and uniqueness. Li (1998) built directly off of the construction of Méléard and Roelly (1992, 1993) to study properties of density processes associated with interacting superprocesses, arriving at a SPDE that forms the foundation of our approach.

Recall, we use $\nu(x, t)$ to denote the density of a superprocess, given it exists. Assuming the interactions manifest only in the reproductive law and that spatial movement follows Brownian motion with diffusion parameter $\sqrt{\mu}$ independent of both X_t and x , Li (1998) proved a result that implies the interacting superprocess on one dimensional trait space has a density $\nu(x, t)$ which is non-negative, integrable, continuous in time and space and satisfies the SPDE

$$\frac{\partial}{\partial t}\nu(x, t) = m(\nu, x)\nu(x, t) + \frac{\mu}{2}\frac{\partial^2}{\partial x^2}\nu(x, t) + \sqrt{V\nu(x, t)}\dot{W}(x, t). \quad (29)$$

As mentioned above, we refer to SPDE (29) as the Stochastic Asexual Gaussian allelic model with Abundance dynamics (abbreviated SAGA). Comparing equation (29) to equation (3.5) of Li (1998), our m and V correspond to Li's b and c respectively. It is important to note that, under the assumptions made in Méléard and Roelly (1992, 1993) and Li (1998), equation (29) is only formal when $m(h, x)$ is bounded across all combinations of $h \geq 0$ and $x \in \mathbb{R}$. However, recalling our condition $m(h, x) \leq r \in \mathbb{R}$, the growth rates we consider are only bounded above. Yet, in the proof of the construction of the interacting superprocess as the limit of rescaled branching diffusions, Méléard and Roelly (1992, 1993) assumed $m(h, x)$ to be bounded to guarantee the total mass process will have finite mean and variance, for finite $t \geq 0$. This allowed the authors to employ a tightness criterion for sequences of measures and show the rescaled processes converge to a superprocess with finite total mass. Li's (1998) result builds directly off of Méléard and Roelly's construction, inheriting the assumption of boundedness for $m(h, x)$. However, in Li (1998), the sufficiency of $m(h, x)$ being bounded above is even more clear since Li works explicitly with a common upperbound for both $m(h, x)$ and V . Hence, one can repeat the necessary proofs replacing the assumption that $m(h, x)$ is bounded with the assumption that $m(h, x)$ is merely bounded above to derive the same results. An alternative approach to establishing this result that allows for our relaxed assumption on the growth rate has carried out by Champagnat, Ferrière, and Méléard (2006) using techniques developed by Evans and Perkins (1994).

With solutions to SPDE (29) well defined for any growth rate bounded above, we can calculate the total mass process $N(t)$ using the mild solution of (29) with $f(x) \equiv 1 \in C_b^2(\mathbb{R})$ (the symbol " \equiv " means equal to for every x). That is,

$$\begin{aligned} N(t) &= N(0) + \int_0^t \int_{\mathbb{R}} \nu(x, s) \left(m(\nu, x) \cdot 1 + \frac{\mu}{2} \frac{\partial^2}{\partial x^2} 1 \right) + 1 \sqrt{V\nu(x, s)} \dot{W}(x, s) ds dx \\ &= N(0) + \int_0^t \bar{m}(s) N(s) dt + \int_0^t \sqrt{VN(s)} d\hat{\mathbf{W}}_s(\sqrt{\nu(x, s)}), \end{aligned} \quad (30)$$

where

$$\bar{m}(t) = \frac{1}{N(t)} \int_{\mathbb{R}} m(\nu, x) \nu(x, t) dx, \quad (31)$$

and

$$\int_0^t d\hat{\mathbf{W}}_s(\sqrt{\nu(x, s)}) = \int_0^t \int_{\mathbb{R}} \frac{\sqrt{\nu(x, s)}}{\sqrt{\int_{\mathbb{R}} \nu(x, s) dx}} \dot{W}(x, s) dx ds. \quad (32)$$

Setting $W_1(t) = \hat{\mathbf{W}}_t(\sqrt{\nu(x, t)})$, we can use traditional stochastic differential notation to write

$$dN = \bar{m}Ndt + \sqrt{VN}dW_1. \quad (33)$$

To find the associated SDE for $\bar{x}(t)$ and $\sigma^2(t)$, we want to repeat the same approach for $f(x) = x, x^2$ and apply Itô's lemma. However, for these cases $f \notin C_b^2(\mathbb{R})$ since f will not be bounded. But if we can show $\int_{\mathbb{R}} (|x| + x^2 + x^4) \nu(x, t) dx < +\infty$ for all $t > 0$ given this condition is satisfied by $\nu(x, 0)$, then we can apply the mild solution of (29) to derive SDE for $\bar{x}(t)$ and $\sigma^2(t)$. To illustrate, let us suppose this is the case. Setting $\tilde{x}(t) = \int_{\mathbb{R}} x \nu(x, t) dx$, we have

$$\tilde{x}(t) = \tilde{x}(0) + \int_0^t \int_{\mathbb{R}} \nu(x, s) m(\nu, x) x + x \sqrt{V \nu(x, s)} \dot{W}(x, s) dx ds. \quad (34)$$

Similarly, setting $\tilde{\sigma}^2(t) = \int_{\mathbb{R}} x^2 \nu(x, t) dx$, we have

$$\tilde{\sigma}^2(t) = \tilde{\sigma}^2(0) + \int_0^t \int_{\mathbb{R}} \nu(x, s) (m(\nu, x) x^2 + \mu) + x^2 \sqrt{V \nu(x, s)} \dot{W}(x, s) dx ds. \quad (35)$$

Since $\bar{x}(t) = \tilde{x}(t)/N(t)$ and $\sigma^2(t) = \tilde{\sigma}^2(t)/N(t) - \bar{x}^2(t)$, we can use Itô's lemma to derive SDE for $\bar{x}(t)$ and $\sigma^2(t)$, which we perform in SM §5.9. We make no attempt in finding sufficient conditions for $\int_{\mathbb{R}} (|x| + x^2 + x^4) \nu(x, t) dx < +\infty$ to hold and hence make no general assertions about the existence or uniqueness of $\bar{x}(t)$ or $\sigma^2(t)$. Regardless, we will later assume $\nu(x, t)$ can be approximated by a Gaussian curve in x for all $t \geq 0$. This assumption implies $\int_{\mathbb{R}} |x|^n \nu(x, t) dx < +\infty$ for all $n \in \mathbb{N}$ and for all $t \geq 0$.

2.3 Equations of evolutionary and demographic dynamics

In SM §5.9 we show SDE for $N(t)$, $\bar{x}(t)$ and $\sigma^2(t)$ can be expressed as

$$dN(t) = \bar{m}(t) N(t) dt + \sqrt{V N(t)} dW_1(t), \quad (36a)$$

$$d\bar{x}(t) = \text{Cov}_t(x, m(\nu, x)) dt + \sqrt{V \frac{\sigma^2(t)}{N(t)}} dW_2(t), \quad (36b)$$

$$d\sigma^2(t) = \text{Cov}_t((x - \bar{x}(t))^2, m(\nu, x)) dt + \left(\mu - V \frac{\sigma^2(t)}{N(t)} \right) dt + \sqrt{V \frac{(x - \bar{x}(t))^4 - \sigma^4(t)}{N(t)}} dW_3(t), \quad (36c)$$

where W_1 , W_2 and W_3 are standard Brownian motions. We note that conditions on the growth rate m to guarantee existence and uniqueness of solutions to (36b) and (36c) have yet to be investigated. However, our results on the deterministic PDE suggest that $m(h, x)$ bounded above and differentiable in both arguments is sufficient. Dividing by dt one can interpret equations (36) as if they are ordinary differential equations, but this not technically rigorous since Brownian motion is nowhere differentiable with respect to time. In SM §5.9 we show that in general W_1 is independent of both W_2 and W_3 , but W_2 and W_3 covary.

There is quite a bit we can learn from expressions (36). Firstly, setting $V = 0$ recovers the deterministic dynamics derived in §2.1. Alternatively, one can take $N(t) \rightarrow \infty$ to recover the deterministic dynamics for $\bar{x}(t)$ and $\sigma^2(t)$. Characteristically, we note the effect of demographic stochasticity on abundance grows with $\sqrt{N(t)}$. Hence, dividing by N , we find the effects of demographic stochasticity on the per-capita growth rate diminish with increased abundance. Relating the response to demographic stochasticity derived here to the effect of random genetic drift derived in classic quantitative genetic theory, if we set $\sigma^2(t) = \sigma^2$ and $N(t) = N$ constant with respect to time, then integrating the stochastic term in equation (36b) over a single unit of time returns a normally distributed random variable with mean zero and variance equal to $V \sigma^2 / N$. In particular, assuming perfect inheritance, when reproductive variance is unity ($V = 1$) this random variable coincides with the effect of random genetic drift on the change in mean trait over a single generation derived using sampling arguments (Lande 1976). There is also an interesting connection with classical population genetics. A fundamental result from early population genetic theory is the expected reduction in diversity due to the chance loss of alleles in finite populations (Fisher 1923; Wright 1931). This expected reduction in diversity due to random genetic drift is captured by the third term in the deterministic component of expression (36c), particularly $-V \sigma^2(t) / N(t)$. The component of SDE (36c) describing random fluctuations

in $\sigma^2(t)$ is more complicated and is proportional to the root of the difference between the centralized fourth moment of $p(x, t)$ and $\sigma^4(t)$.

These expressions can be used to investigate the dynamics of the mean and variance for general $\nu(x, t)$. However, in the next subsection we simplify these expressions by approximating $\nu(x, t)$ with a Gaussian curve. By assuming $\nu(x, t)$ is Gaussian for $t \geq 0$, we guarantee the existence of $\bar{x}(t)$ and $\sigma^2(t)$ for all $t \geq 0$. Furthermore, in SM §5.9 we show that under the Gaussian case W_1, W_2 and W_3 are independent.

2.3.1 Particular results assuming a Gaussian phenotypic distribution

By assuming $\nu(x, t)$ can be approximated by a Gaussian curve for each $t \geq 0$, expressions (36a), (36b) and (36c) transform into efficient tools for deriving the dynamics of populations given a fitness function $m(\nu, x)$. Gaussian phenotypic distributions are often obtained through Gaussian, exponential or weak selection approximations together with a simplified model of inheritance and random mating (Lande 1980; Turelli 1984, 1986, 2017; Bürger 2000). Alternatively, it has been shown that a Gaussian distribution can provide a reasonable approximation even when selection is strong and non-Gaussian (Turelli and Barton 1994). However, our approach adds an additional layer of difficulty. Even with Gaussian selection, the resulting solution to SPDE (29) will only be a Gaussian curve in expectation, assuming a Gaussian curve as the initial condition. Yet this difficulty is not as challenging as it may first appear. Indeed, since SPDE (29) can be derived as a diffusion limit we know that, under the appropriate assumptions on selection, genetic architecture and reproduction, the stochastic departure from a Gaussian curve is negligible when the ratio V/N is small (i.e., when the variance in reproductive output is much smaller than the population size). In SM §5.8 we demonstrate this result using numerical methods. Mathematically, this requirement restricts model parameters to regions that maintain large population sizes. Biologically, this implies populations are not at risk of extinction. Hence, models developed in this framework are not suitable for studying colonization-extinction dynamics or evolutionary rescue. Allowing for these restrictions, we may safely assume that ν is approximately Gaussian and justify writing

$$\nu(x, t) = \frac{N(t)}{\sqrt{2\pi\sigma^2(t)}} \exp\left(-\frac{(x - \bar{x}(t))^2}{2\sigma^2(t)}\right). \quad (37)$$

Under this assumption we find in SM §5.6 the results (suppressing the dependency on t)

$$\text{Cov}(x, m) = \sigma^2 \left(\frac{\partial \bar{m}}{\partial \bar{x}} - \overline{\frac{\partial m}{\partial x}} \right), \quad (38)$$

$$\text{Cov}\left((x - \bar{x})^2, m\right) = 2\sigma^4 \left(\frac{\partial \bar{m}}{\partial \sigma^2} - \overline{\frac{\partial m}{\partial \sigma^2}} \right) \quad (39)$$

and $\overline{(x - \bar{x})^4} = 3\sigma^4$. Equation (38) is the continuous time equivalent to equation (9) in Lande (1976). In particular, these results imply

$$d\bar{x} = \sigma^2 \left(\frac{\partial \bar{m}}{\partial \bar{x}} - \overline{\frac{\partial m}{\partial x}} \right) dt + \sqrt{V \frac{\sigma^2}{N}} dW_2, \quad (40a)$$

$$d\sigma^2 = 2\sigma^4 \left(\frac{\partial \bar{m}}{\partial \sigma^2} - \overline{\frac{\partial m}{\partial \sigma^2}} \right) dt + \left(\mu - V \frac{\sigma^2}{N} \right) dt + \sigma^2 \sqrt{\frac{2V}{N}} dW_3. \quad (40b)$$

These equations allow us to derive the response in trait mean and variance by taking derivatives of fitness, a much more straightforward operation than calculating a covariance for general phenotypic distributions. Note that in the above expressions, the partial derivatives of \bar{m} represent frequency independent selection and the averaged partial derivatives of m represent frequency dependent selection. This relationship has already been pointed out by Lande (1976) for the evolution of the mean trait, but here we see an analogous relationship holds also for the evolution of trait variance.

In the next subsection we generalize this result to the case when traits are imperfectly inherited. In this case, the phenotypic variance σ^2 is replaced by a genetic variance G . This genetic variance represents the component of the variance in expressed traits σ^2 explained by additive effects of different alleles among genetic loci encoding for the focal phenotype (Roughgarden 1979; Bulmer 1980; Lynch and Walsh 1998). It is therefore fitting that G is referred to as the additive genetic variance.

2.3.2 The evolution of additive genetic variance

To model imperfect heritability we consider the relationship between expressed phenotypes $x \in \mathbb{R}$ and associated genetic values $g \in \mathbb{R}$ known as *breeding values*. The breeding value of an individual is the sum of additive effects of the alleles carried by the individual on its expressed trait. Since our derivations of evolutionary equations are based on branching processes that assume asexually reproducing populations (§2.2.3), the additive genetic variance G is just the variance of breeding values in a population. For a detailed treatment of breeding values and additive genetic variances, see Bulmer (1980) and Lynch and Walsh (1998).

Our treatment of the relationship between breeding values and expressed traits follows classical quantitative genetic assumptions such as those used in the seminal paper by Lande (1975) to investigate the maintenance of genetic variation. In particular, we assume that the expressed trait for any given individual is independent of environmental conditions and normally distributed around their breeding value with variance η . Hence, $\sigma^2 = G + \eta$. In the case that all of the effects of alleles on an expressed trait are additive, η is known as the *variance of environmental deviation* (Lande 1975; Lynch and Walsh 1998). For a given breeding value, we denote the probability density of a randomly drawn expressed trait by $\psi(x, g)$. Hence,

$$\psi(x, g) = \frac{1}{\sqrt{2\pi\eta}} \exp\left(-\frac{(x - g)^2}{2\eta}\right). \quad (41)$$

To include this relationship in our framework, we write $\rho(g, t)$ as the abundance density of breeding values at time t so that $\int_{-\infty}^{+\infty} \rho(g, t) dg = \int_{-\infty}^{+\infty} \nu(x, t) dx = N(t)$. We switch our focus from directly modelling the evolution of $\nu(x, t)$ to modelling the evolution of $\rho(g, t)$. Once $\rho(g, t)$ is determined, we can compute $\nu(x, t)$ via

$$\nu(x, t) = \int_{-\infty}^{+\infty} \rho(g, t) \psi(x, g) dg. \quad (42)$$

However, since selection acts on expressed phenotypes, we use the assumed relationship between breeding values and expressed traits to calculate the fitness of breeding values. To motivate the approach taken, consider the problem of inferring the breeding value of an individual given its expressed trait x . Denote \mathbf{g} a random variable representing the unknown breeding value. Under this model of inheritance we know x is a random sample from a normal distribution with mean \mathbf{g} and variance η . Maximizing likelihood suggests x is our best guess for \mathbf{g} , but the actual value of \mathbf{g} is normally distributed around x with the variance η . Hence, for fixed x , we obtain $\psi(x, g)$ as the probability density of \mathbf{g} . Thus, the mean fitness of a breeding value g across all individuals carrying g can be written as

$$m^*(\rho, g) = \int_{-\infty}^{+\infty} m(\nu, x) \psi(x, g) dx. \quad (43)$$

This is similar to the approach taken by Kimura and Crow (1978) to calculate the overall effects of selection for expressed characters onto the changes in the distribution of alleles encoding those characters. However, instead of focusing on the frequencies of alleles at particular loci, our results focus on the densities of breeding values. With the relationship between $m(\nu, x)$ and $m^*(\rho, g)$ established, we define the evolution of $\rho(g, t)$ by the SPDE

$$\dot{\rho}(g, t) = m^*(\rho, g) \rho(g, t) + \frac{\mu}{2} \frac{\partial^2}{\partial^2 g} \rho(g, t) + \sqrt{V \rho(g, t)} \dot{W}(g, t). \quad (44)$$

Equation (44) is a stochastic generalization of the deterministic PDE (7) from §2.1, but describes the evolution of the distribution of breeding values instead of expressed characters. However, whether modelling

expressed characters or breeding values, we refer to SPDE of the form (44) as Stochastic Asexual Gaussian allelic models with Abundance dynamics (abbreviated SAGA). By replacing $\psi(x, g)$ with different probability densities produces different developmental models. This includes densities that may depend on environmental variables and hence model phenotypic plasticity. To leave room for the naming of other models where $\psi(x, g)$ is Gaussian, we refer to the model of development we have chosen as the *centered* Gaussian developmental model. In §2.2 we review the origins of equation (44) and provide some theory to help make sense of it, particularly the term \dot{W} .

Assuming $\rho(g, t)$ is Gaussian implies its mode coincides with \bar{x} . Furthermore, since $\sigma^2 = G + \eta$, we can use equation (43) and the chain rule from calculus (see SM §5.10) to find

$$\frac{\partial \bar{m}}{\partial G} = \frac{\partial \bar{m}}{\partial \sigma^2} \frac{\partial \sigma^2}{\partial G} = \frac{\partial \bar{m}}{\partial \sigma^2}, \quad (45a)$$

$$\frac{\partial \bar{m}}{\partial G} = \frac{\partial \bar{m}}{\partial \sigma^2} \frac{\partial \sigma^2}{\partial G} = \frac{\partial \bar{m}}{\partial \sigma^2}. \quad (45b)$$

Thus, equations (40) become

$$d\bar{x} = G \left(\frac{\partial \bar{m}}{\partial \bar{x}} - \frac{\partial \bar{m}}{\partial \bar{x}} \right) dt + \sqrt{V \frac{G}{N}} dW_2, \quad (46a)$$

$$dG = 2G^2 \left(\frac{\partial \bar{m}}{\partial G} - \frac{\partial \bar{m}}{\partial G} \right) dt + \left(\mu - V \frac{G}{N} \right) dt + G \sqrt{\frac{2V}{N}} dW_3. \quad (46b)$$

From expressions (46) we see that, under this model of inheritance, focusing on additive genetic variance G instead the variance in expressed traits σ^2 makes no structural changes to the basic equations describing the dynamics of populations. In the next section, we make use of these expressions to develop a model of diffuse coevolution in a guild of S species competing along a resource continuum.

3 A model of diffuse coevolution

3.1 Formulation

In this section we demonstrate the use of our framework by developing a model of diffuse coevolution across a guild of S species whose interactions are mediated by resource competition along a single niche axis. Because our approach treats abundance dynamics and evolutionary dynamics simultaneously, this model allows us to investigate the relationship between selection gradients and competition coefficients, which we carry out in what follows.

The dynamics of phenotypic distributions and abundances have been derived above and so the only task remaining is the formulation of a fitness function. Our approach mirrors closely the theory developed by MacArthur and Levins (1967), Levins (1968) and MacArthur (1969, 1970, 1972). The most significant difference, aside from allowing evolution to occur, is the treatment of resource quality, which we replace with a model of abiotic stabilizing selection. A derivation is provided in SM §5.11.

For species i we inherit the above notation for trait value, distribution, average, variance, abundance, etc except with an i in the subscript. Real world examples of niche axes include the body size of prey for lizard predators and the date of activity in a season for pollinators competing for floral resources. For mathematical convenience, we model the axis of resources by the real line \mathbb{R} . The value of a resource along this axis is denoted by the symbol ζ . For an individual in species i , we assume the resource utilization curve u_i can be written as

$$u_i(\zeta, x_i) = \frac{U_i}{\sqrt{2\pi w_i}} \exp \left(-\frac{(x_i - \zeta)^2}{2w_i} \right). \quad (47)$$

We further assume the niche center x_i is normally distributed among individuals in species i , but the niche breadth w_i and total niche utilization U_i are constant across individuals in species i and therefore cannot evolve. Suppose $\theta_i \in \mathbb{R}$ is the optimal location along the niche axis for species i such that, in the absence of competition, individuals leave on average Q_i offspring when concentrated at θ_i . We capture the rate by which the fitness falls as niche location ζ leaves the optimum θ_i by the parameter $A_i \geq 0$. Hence, abiotic stabilizing selection along the resource axis can be modelled by the curve

$$e_i(\zeta) = Q_i \exp\left(-\frac{A_i}{2}(\theta_i - \zeta)^2\right). \quad (48)$$

The effect of abiotic stabilizing selection on the fitness for an individual of species i with niche location x_i is then given by

$$\int_{-\infty}^{+\infty} e_i(\zeta) u_i(\zeta, x_i) d\zeta = \frac{Q_i U_i}{\sqrt{A_i w_i + 1}} \exp\left(-\frac{A_i}{2(A_i w_i + 1)}(\theta_i - x_i)^2\right). \quad (49)$$

To determine the potential for competition between individuals with niche locations x_i and x_j , belonging to species i and j respectively, we compute the niche overlap

$$\mathcal{O}_{ij}(x_i - x_j) = \int_{-\infty}^{+\infty} u_i(\zeta, x_i) u_j(\zeta, x_j) d\zeta = \frac{U_i U_j}{\sqrt{2\pi(w_i + w_j)}} \exp\left(-\frac{(x_i - x_j)^2}{2(w_i + w_j)}\right). \quad (50)$$

A notable criticism of using niche overlap to measure the intensity of competition points to cases where populations competing on multiple niche axes exhibit overlap on at least one of the axes, but no overall niche overlap (Holt 1987). Thus niche overlap on lower-dimensional projections of some multivariate niche space does not imply the populations compete. To illustrate with a simple example, consider two populations competing for space on the plane \mathbb{R}^2 . If the spatial distributions of the two populations overlap, then they will overlap on both spatial axes. However, if the populations do not overlap on at least one of the spatial axes, they will have no overall spatial overlap. Furthermore, even if the species overlap on both spatial axes, they need not have any overall spatial overlap. This final result corresponds to the fact that components of niche space do not necessarily interact multiplicatively to determine the consequences for the intensity of competition. In another component of Holt's (1987) critique, an argument is made for the potential of competition occurring without any overlap in niche space. However, this argument is based on the practical difficulty of identifying every resource axis populations are competing on and how these axes interact to determine fitness consequences. Our model avoids these caveats by assuming competition only occurs along a single dimensional resource gradient.

To map the degree of niche overlap to fitness, we assume competition between individuals with niche locations x_i and x_j additively decreases the Malthusian fitness for the individual in species i by $c_i \mathcal{O}_{ij}(x_i - x_j)$ for some $c_i \geq 0$. We refer to c_i as the sensitivity to competition for species i . The term $c_i \mathcal{O}_{ij}(x_i - x_j)$ coincides with a special case of a term used to capture competition in Dawson's geostochastic logistic model, an SPDE model developed to study the combined effects of demographic stochasticity, spatial dispersion and locally finite carrying capacity (Dawson 1978). In relation to the example fitness function discussed in §2.1, consider $\kappa(x_i - x_j) = \mathcal{O}_{ij}(x_i - x_j)$. In SM §5.11 we combine our treatment of resource competition with equations (36a), (46a) and (46b) to find

$$dN_i = \left\{ R_i - \frac{a_i}{2} \left((\bar{x}_i - \theta_i)^2 + G_i + \eta_i \right) - c_i \sum_{j=1}^S N_j U_i U_j \sqrt{\frac{b_{ij}}{2\pi}} e^{-\frac{b_{ij}}{2}(\bar{x}_i - \bar{x}_j)^2} \right\} N_i dt + \sqrt{V_i N_i} dW_1, \quad (51a)$$

$$d\bar{x}_i = \left\{ a_i G_i (\theta_i - \bar{x}_i) - c_i G_i \left(\sum_{j=1}^S N_j U_i U_j b_{ij} (\bar{x}_j - \bar{x}_i) \sqrt{\frac{b_{ij}}{2\pi}} e^{-\frac{b_{ij}}{2}(\bar{x}_i - \bar{x}_j)^2} \right) \right\} dt + \sqrt{V_i \frac{G_i}{N_i}} dW_2, \quad (51b)$$

$$dG_i = \left\{ c_i G_i^2 \left(N_i U_i^2 b_{ii} \sqrt{\frac{b_{ii}}{2\pi}} + \sum_{j=1}^S N_j U_i U_j b_{ij} (1 - b_{ij}(\bar{x}_i - \bar{x}_j)^2) \sqrt{\frac{b_{ij}}{2\pi}} e^{-\frac{b_{ij}}{2}(\bar{x}_i - \bar{x}_j)^2} \right) + \mu_i - a_i G_i^2 - V_i \frac{G_i}{N_i} \right\} dt + G_i \sqrt{\frac{2V_i}{N_i}} dW_3, \quad (51c)$$

where

$$R_i = \ln \left(\frac{Q_i U_i}{\sqrt{1 + A_i w_i}} \right), \quad (52a)$$

$$a_i = \frac{A_i}{1 + A_i w_i}, \quad (52b)$$

$$b_{ij}(t) = b_{ji}(t) = (w_i + w_j + \eta_i + \eta_j + G_i(t) + G_j(t))^{-1}, \quad (52c)$$

$$c_i \geq 0. \quad (52d)$$

Despite the convoluted appearance of system (51), there are some nice features that reflect biological reasoning. For example, the dynamics of abundance are just a generalization of Lotka-Volterra dynamics. In particular, the effect of competition with species j on the fitness of species i grows linearly with N_j . However, as biotic selection pushes \bar{x}_i away from \bar{x}_j , the effect of competition with species j on the fitness of species i rapidly diminishes, reflecting a reduction in niche overlap. The divergence of \bar{x}_i and \bar{x}_j due to competition is referred to in the community ecology literature as character displacement. We also see that the fitness of species i drops quadratically with the difference between \bar{x}_i and the abiotic optimum θ_i . Hence, abiotic selection acts to pull \bar{x}_i towards θ_i . The response in mean trait \bar{x}_i to natural selection is proportional to the amount of heritable variation in the population, represented by the additive genetic variance G_i . However, we have that G_i is itself a dynamic quantity. Under our model, abiotic stabilizing selection erodes away heritable variation at a rate that is independent of both N_i and \bar{x}_i . The effect of competition on G_i is a bit more complicated. When $b_{ij}(\bar{x}_i - \bar{x}_j)^2 < 1$, competition with species j acts as diversifying selection which tends to increase the amount of heritable variation. However, when $b_{ij}(\bar{x}_i - \bar{x}_j)^2 > 1$, competition with species j acts as directional selection and reduces G_i . In the following subsections we demonstrate the behavior of system (51) by plotting numerical solutions and investigate implications for the relationship between the strength of ecological interactions and selection.

3.2 Community dynamics

For the sake of illustration we numerically integrated system (51) for a richness of $S = 100$ species. We assumed homogeneous model parameters across species in the community as summarized by Table 2. We repeated numerical integration under the two scenarios of weak and strong competition. For the first scenario of weak competition we set $c = 1.0 \times 10^{-7}$ and for the second scenario of strong competition we set $c = 5.0 \times 10^{-6}$. With these two sets of model parameters, we simulated our model for 1000.0 units of time. For both scenarios, we initialized the trait means to $\bar{x}_i = 0.0$, additive genetic variances to $G_i = 10.0$ and abundances to $N_i = 1000.0$ for each $i = 1, \dots, S$.

Temporal dynamics for each scenario are provided in Figure 3. This figure suggests weaker competition leads to smoother dynamics and a higher degree of organization within the community. Considering expression (51a) we note that, all else equal, relaxed competition allows for larger growth rates which promote greater abundances. From (51a) we also note that the per-capita effects on demographic stochasticity diminish with abundance. To see this, divide both sides by N_i . Inspecting expressions (51b) and (51c), we see that larger abundances also erode the effects of demographic stochasticity on the evolution of mean trait and additive genetic variance. These effects were already noted in §2.3, and thus are not a consequence of our model of

coevolution per-se, but we revisit them here since Figure 3 demonstrates the importance of demographic stochasticity in structuring ecological communities even when populations are very large. Hence, contrary to the common assumption that stochastic effects can be ignored for large populations, we find that minute asymmetries generated by demographic stochasticity remain significant drivers of community structure. In particular, we initialized the species with identical state variables and model parameters, but found an enormous amount of asymmetry and even some potential phase changes. In the following two paragraphs we describe the natural history of the community as illustrated in Figure 3.

We begin by describing the weak competition scenario. After about 125.0 units of time, the community appears to have shaken off the initial conditions and entered into a qualitatively distinct phase of dynamics. Aside from a few outliers, most of the species remain clustered together in their state variables. This lasts for approximately 375.0 units of time until, at around time 500.0, a drastic change occurs. At this moment the tightly packed cluster of species begins to fan out in all three state variables. Simultaneously, we observe large a shift in mean traits for higher values and in additive genetic variances for lower values. Upon inspecting our calculations, we diagnose the reason for this shift. The outlier species that were initially pushed away from the common abiotic optimum (0.0 in this case) evolved a significant reduction in the amount of heritable variation ($\approx 60\%$) due to directional selection induced by competition. This reduction in heritable variation slowed adaptation, causing these species to linger on the outskirts of niche space, some longer than others. In the meantime the rest of the community, being tightly packed, experienced greater competition which led to diminished abundances for these species and caused some members of the core group to veer away from the abiotic optimum. The reduced abundances of the core group led to reduced competition overall. As a result, the outlier populations were given a slight increase in growth rate, enough to allow them to increase their abundances orders of magnitude higher than the species in the core group and giving them more weight in driving the evolution of other species. Many of these heavy-hitting outlier species had already been maintaining negative mean traits, but around time 500.0 the high abundance species with positive mean traits began to experience enough intraspecific competition to override interspecific competition. This generated a net selection gradient and associated evolutionary response towards the abiotic optimum. The sudden imbalance of these high abundance species effectively induced a single large competitive exclusion event pushing the majority of the community far away from the abiotic optimum. After this shift the cluster began to slowly bloom in all three state variables as species took advantage of novel asymmetries in their competitive abilities mediated by a new distribution of mean trait values across the community. About 125.0 units of time later, the community reached a qualitatively new phase of dynamics. If we kept running the numerical integrator, we would continue to see similar drama unfolding over and over again as minute stochastic changes contribute to asymmetries which slowly build into drastic shifts.

The strong competition scenario is not quite as showy. Although the dynamics of trait means and variances tend to be far more stochastic than in the weak competition scenario, the community overall appears to quickly reach some statistical equilibrium and remain there. However, the abundances across all species in the community are very low due to competition sensitivities being an order of magnitude higher than in the weak competition case. Most of the species maintain abundances greater than 1000.0, but we found one species that dropped to an abundance of about 50.0. If we let the numerical integrator run long enough in this case, we will likely see many of the species go extinct.

Finding ways to interpret simulated dynamics provides a useful arena to exercise biological reasoning. However, it does not fulfill our desire to quantify the patterns and processes present in competing communities. In the next subsection we take a step in this direction by using our model to derive formula for selection gradients and competition coefficients. To investigate their relationship, we calculate their covariances using simplifying assumptions on species abundances and intraspecific trait variances. We then investigate how these covariances change with the ratio of variance of interspecific mean traits to variance of intraspecific individual traits and use a numerical approach to investigate correlations between the strength of pairwise coevolution and competition coefficients.

Table 2: Values of model parameters used for numerical integration.

Parameter	Description	Value
R	innate growth rate, see §3.3	1.0
θ	abiotic optimum	0.0
a	strength of abiotic selection	0.01
c	sensitivity to competition	$\{1.0 \times 10^{-7}, 5.0 \times 10^{-6}\}$
w	niche breadth	0.1
U	total niche use	1.0
η	segregation variance	1.0
μ	mutation rate	1.0×10^{-7}
V	variance of reproductive output	5.0

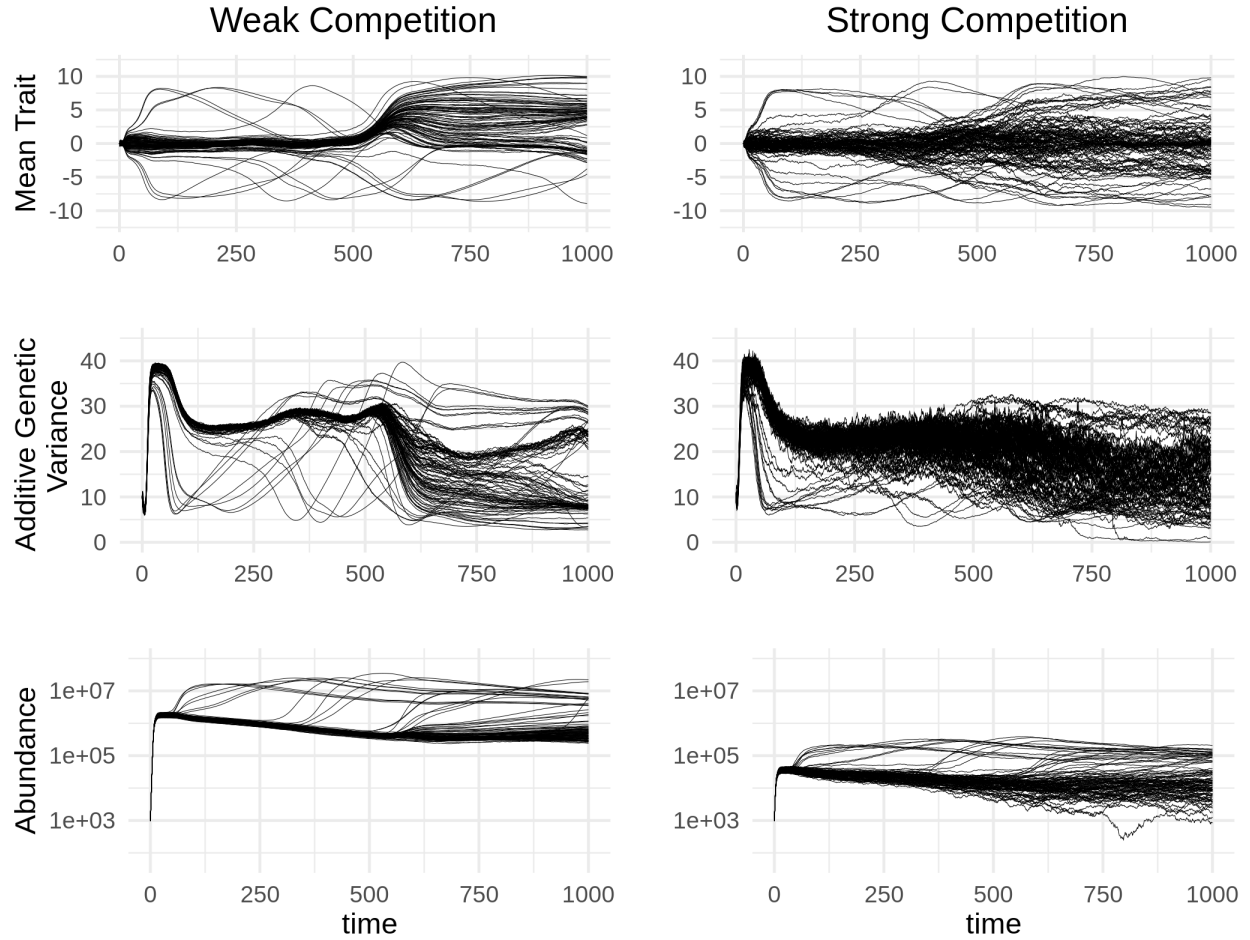

Figure 3: Temporal dynamics of mean trait (top), additive genetic variance (middle) and abundance (bottom) for the scenario of weak competition (left) and strong competition (right).

3.3 The relation between the strength of ecological interactions and coevolution

Relating our treatment of resource competition to modern coexistence theory (Chesson 2000), the absolute competition coefficient α_{ij} becomes a dynamical quantity that can be written as

$$\alpha_{ij}(t) = \frac{c_i}{r_i(t)} \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} p_i(x, t) p_j(y, t) \mathcal{O}_{ij}(x, y) dx dy = \frac{c_i U_i U_j}{r_i(t)} \sqrt{\frac{b_{ij}(t)}{2\pi}} \exp\left(-\frac{b_{ij}(t)}{2} (\bar{x}_i(t) - \bar{x}_j(t))^2\right), \quad (53)$$

where

$$r_i(t) = R_i - \frac{a_i}{2} \left((\bar{x}_i(t) - \theta_i)^2 + G_i(t) + \eta_i \right). \quad (54)$$

Hence, $dN_i(t)$ can be expressed as

$$dN_i(t) = r_i(t) \left(1 - \sum_{j=1}^S \alpha_{ij}(t) N_j(t) \right) N_i(t) dt + \sqrt{V_i N_i(t)} dW_1(t). \quad (55)$$

Note that although $r_i(t)$ is referred to in the coexistence literature as the intrinsic growth rate of the population, R_i is a deeper intrinsic quantity. For now we refer to R_i as the *innate* growth rate. Previous work, to list just a few citations in this literature, has shown the importance of demographic stochasticity (Turelli 1980; Schreiber 2017) and evolutionary dynamics (Case and Taper 1986; Schreiber, Patel, and terHorst 2018) in determining coexistence of competing species. However, these studies consider evolution and demographic stochasticity separately. To our knowledge, there are no rigorous theoretical investigations of coexistence that account for evolutionary dynamics of quantitative characters and demographic stochasticity simultaneously and, in particular, no studies combining these processes that also include the evolution of additive genetic variance. In fact, only recently have rigorous theoretical investigations successfully combined these processes to understand persistence of a single population (Gomulkiewicz, Krone, and Remien 2017). Even so, these authors focused on a single species model with a finite number of types (i.e., a population genetic model). With the connection outlined in this section formally established, researchers may pursue a postmodern coexistence theory that naturally includes both the evolutionary dynamics of quantitative characters and the effects of demographic stochasticity in a simple synthetic framework.

In SM §5.11 we show that the standardized directional selection gradient (sensu Lande and Arnold 1983) induced by species j on species i can be computed as

$$\beta_{ij}(t) = c_i U_i U_j N_j(t) b_{ij}(t) (\bar{x}_i(t) - \bar{x}_j(t)) \sqrt{\frac{b_{ij}(t)}{2\pi}} \exp\left(-\frac{b_{ij}(t)}{2} (\bar{x}_i(t) - \bar{x}_j(t))^2\right). \quad (56)$$

Our notation differs from Lande and Arnold (1983) in that subscripts here denote species instead of components of multivariate traits and we drop the prime that distinguishes between selection gradients and standardized selection gradients.

Metric of pairwise coevolution

Below we investigate the correspondence of interaction intensity and coevolutionary change. However, we can already identify one major discrepancy; α_{ij} is maximized when $\bar{x}_i = \bar{x}_j$, but $\beta_{ij} = 0$ under the same condition. We therefore include in our metric of selection the standardized stabilizing selection gradient γ which measures the effect of stabilizing or disruptive selection on phenotypic variance (Lande and Arnold 1983). In SM §5.11 we show that the standardized stabilizing selection gradient induced by species j on species i can be computed as

$$\gamma_{ij}(t) = c_i U_i U_j N_j(t) b_{ij}(t) \left(1 - b_{ij}(t) (\bar{x}_i(t) - \bar{x}_j(t))^2\right) \sqrt{\frac{b_{ij}(t)}{2\pi}} \exp\left(-\frac{b_{ij}(t)}{2} (\bar{x}_i(t) - \bar{x}_j(t))^2\right). \quad (57)$$

808 To measure the total evolutionary change in species i induced by species j , we form the metric $\Psi_{ij} =$
809 $|\beta_{ij}| + |\gamma_{ij}|$. Figure 4 displays the joint distribution of $\mathfrak{C}_{ij} = \Psi_{ij} \Psi_{ji}$, our metric of pairwise coevolution, and
810 the product of competition coefficients $\alpha_{ij} \alpha_{ji}$ for two simulated communities, both with richness $S = 1000$.
811 The solid contour represents the case of relatively high sensitivity to competition ($c = 5 \times 10^{-7}$) and the
812 dashed contour represents the case of relatively weak sensitivity to competition ($c = 1 \times 10^{-8}$). In both
813 cases we see that \mathfrak{C}_{ij} and $\alpha_{ij} \alpha_{ji}$ are, essentially, unrelated. However, this depiction is only representative
814 of a specific set of parameters. Next, we provide analytical approximations of the covariance between
815 selection gradients and competition coefficients and a numerical estimate for the relationship between pairwise
816 coevolution and competition coefficients for a range of parameters.

Figure 4: Bivariate distributions of competition coefficients (y-axis) and pairwise coevolution (x-axis) under the scenarios of weak competition (dashed line) and strong competition (solid line) after simulating for $t = 1000.0$ units of time. Simulations were ran for $S = 1000$ species. Parameters are the same as in Table 2, except we used $c = 1 \times 10^{-8}$ for weak competition and $c = 5 \times 10^{-7}$ for strong competition in order to account for increased species richness.

817 Covariance of selection and competition as a function of diversity

818 We now make use of the expressions derived for competition coefficients and selection gradients to investigate
819 their relationship. As a first pass, let us assume all model parameters are equivalent across species and that
820 each species has the same abundance and trait variance. Let us further assume that richness S is large and
821 the distribution of mean trait values is normal with mean \bar{x} , variance $V_{\bar{x}}$ and density $f_{\bar{x}}$. Such assumptions
822 are typical when deriving analytical results in the field of theoretical coevolutionary community ecology
823 (Nuismer, Jordano, and Bascompte 2012; Nuismer, Week, and Aizen 2018). If \bar{x} is near θ and $V_{\bar{x}}$ is much
824 smaller than $|2R/a - G - \eta|$, then we may approximate r_i with

$$\bar{r} = \int_{-\infty}^{+\infty} \left(R - \frac{a}{2} ((\bar{x} - \theta)^2 + G + \eta) \right) f_{\bar{x}}(\bar{x}) d\bar{x} = R - \frac{a}{2} ((\bar{x} - \theta)^2 + V_{\bar{x}} + G + \eta). \quad (58)$$

In SM §5.12 we use these assumptions to calculate the first and second order moments describing the joint distribution of competition coefficients and selection gradients across the community. We find that the covariance between linear selection gradients and competition coefficients are zero due to the symmetry implied by our assumptions. However, setting $\alpha(\bar{x}_i, \bar{x}_j) = \alpha_{ij}$, $\beta(\bar{x}_i, \bar{x}_j) = \beta_{ij}$ and $\gamma(\bar{x}_i, \bar{x}_j) = \gamma_{ij}$, the covariances between the magnitude of linear selection gradients and competition coefficients and between stabilizing selection gradients and competition coefficients can be written as

$$\text{Cov}_{f_{\bar{X}}}(\alpha, |\beta|) = \frac{2c^2b^2U^4N}{\pi\bar{r}} \sqrt{\frac{V_{\bar{X}}}{2\pi}} \left(\frac{1}{(1+8bV_{\bar{X}})^{3/4}} - \frac{1}{(1+4bV_{\bar{X}})^{3/4}(1+2bV_{\bar{X}})^{1/2}} \right), \quad (59a)$$

$$\text{Cov}_{f_{\bar{X}}}(\alpha, \gamma) = \frac{c^2b^2U^4N}{2\pi\bar{r}} (1-2bV_{\bar{X}}) \left(\frac{1}{\sqrt{1+4bV_{\bar{X}}}} - \frac{1}{1+2bV_{\bar{X}}} \right). \quad (59b)$$

Figure 5: Curves representing the covariance between the magnitude of linear selection gradients and competition coefficients (left) and between stabilizing selection gradients and competition coefficients (right) as a function of $2bV_{\bar{X}}$ which is approximately equal to the ratio of variance in mean traits among species to the intraspecific trait variance. In both plots we set $c = 1.0 \times 10^{-4}$, $b = 0.1$, $\bar{r} = 0.1$ and $N = 1.0 \times 10^{10}$ and let $V_{\bar{X}}$ vary.

For fixed c, b, \bar{r} and N , we visualize these relationships in Figure 5. To gain insight into the relationship between selection gradients and competition coefficients, note that our assumptions in this section imply $b^{-1} = 2(\sigma^2 + w)$. If we further assume $\sigma^2 + w \approx \sigma^2$, then $2bV_{\bar{X}} \approx V_{\bar{X}}/\sigma^2$. That is, when populations are generalists and are comprised of specialist individuals, the value $2bV_{\bar{X}}$ is approximately equal to the ratio of interspecific mean trait variation to intraspecific individual trait variation. Hence, for both covariances we see that there is no relationship between selection gradients and competition coefficients when this ratio is zero. From equation (59a) we can use numerical optimization to find that when $V_{\bar{X}}/\sigma^2 \approx 1.25$ the relationship between the magnitudes of linear selection gradients and competition coefficients disappears, but when (approximately) $V_{\bar{X}}/\sigma^2 < 1.25$ (> 1.25), this covariance becomes negative (positive). Equation (59b) states that when $V_{\bar{X}}/\sigma^2$ is approximately equal to one (or slightly larger), there is no expected relationship between competition coefficients and quadratic selection gradients. However, when $V_{\bar{X}}/\sigma^2 < 1.0$ (> 1.0), then we expect a positive (negative) relationship between α and γ . These results are true regardless of the chosen parameter values. In SM §5.12 we use simulations of system (51) to show that these results do not qualitatively differ when allowing for heterogeneous population sizes and additive genetic variances across species.

From a biological perspective, if the ratio $V_{\bar{X}}/\sigma^2$ is small, then species are packed tightly in phenotypic space. In our model this occurs when abiotic stabilizing selection is much stronger than competition ($a \gg c$). This

causes species to overlap more in niche space (i.e., large α) and creates disruptive selection for greater intraspecific variance (i.e., positive γ), which explains the positive region of covariance between α and γ . However, as species begin to overlap in niche space, directional selection begins to vanish (i.e., small $|\beta|$), leading to a negative covariance between α and $|\beta|$. In the limiting case that two species have perfectly overlapping niches, they will exhibit zero directional selection since a shift in either direction will yield the same fitness advantages.

In the opposite scenario where competition is much stronger than abiotic stabilizing selection ($c \gg a$), species will not evolve to be as tightly packed and instead their niche-centers will be spread out with little overlap in their resource utilization curves (i.e., small α). In this case biotic directional selection will be strong (i.e., large $|\beta|$), particularly for species towards the outer regions of niche space due to asymmetric fitness advantages conferred by shifts in niche-centers. This leads to a positive covariance between α and $|\beta|$. However, as noted above, this directional selection will also erode away at standing heritable variation (i.e., negative γ), reducing the rate at which adaptation can occur and creating a negative covariance between α and γ .

In summary, we see the relation between competition coefficients and selection is highly non-trivial and depends on the relative magnitudes of different ecological processes shaping the community. However, this does not address the relation between competition coefficients and coevolution per se. In SM §5.12 we show that calculating a formula for the covariance between competition coefficients and the metric of coevolution \mathfrak{C} introduced above provides a difficult analytical challenge. Instead of confronting this challenge we build on our numerical approach used to justify analytical approximations of $\text{Cov}_{f_{\bar{x}}}(\alpha, |\beta|)$ and $\text{Cov}_{f_{\bar{x}}}(\alpha, \gamma)$ to approximate the correlation of α and \mathfrak{C} . This numerical approach inherits the assumptions of homogeneous background parameters such as the mutation rate μ and abiotic optima θ , but allows us to relax the assumption that N and G are constant across species and time.

In particular, we numerically integrated system (51) for $T_1 = 1000.0$ units of time and then continued to integrate for $T_2 = 1000.0$ units of time. We then calculate the covariance between the quantities α and \mathfrak{C} across $S = 100$ species for each of the last T_2 time steps. We assume the temporal average of these covariances across the last T_2 units of time approximates the expectation at equilibrium. We repeated this approach for randomly drawn a and c until our sample size reached 1000. In Figure 6 we plot the temporally averaged values of $\text{Cov}_{f_{\bar{x}}}(\alpha, \mathfrak{C})$ against the sensitivity to competition c . Using a cubic regression, we see the correlation of coevolutionary selection gradients and competition coefficients is negative at variance ratios below 0.5, zero at variance ratios between 0.5 and 1.0, and drops below zero again at variance ratios above 1.0.

Figure 6: Numerical estimates for the correlation of the strength of coevolution measured by \mathfrak{C} and competition coefficients α plotted against the variance of mean traits among species divided by the mean variance of traits within species. Each dot represents the result from a single simulation. The red line is a cubic regression.

4 Conclusion

We have introduced an approach to derive models of evolutionary ecology using the calculus of white noise and coined SAGA, a SPDE model of phenotypic evolution that accounts for demographic stochasticity. From SAGA we derived SDE that track the evolution of abundance, mean trait and additive genetic variance. Observing the expressions of these SDE we find the effects of demographic stochasticity on the evolution of mean trait and additive genetic variance characterize the effects of random genetic drift. By considering the statistics of random samples, this has previously been in models of fixed population size in discrete time (Lande 1976). However, we have shown random genetic drift is a result of demographic stochasticity for populations with fluctuating abundances in continuous time. To illustrate the relevance of our approach to studies of evolutionary ecology, we combined our SDE with classical competition theory to derive a model of diffuse coevolution and used this model to investigate the relationship between selection gradients and competition coefficients. This work demonstrates that connecting contemporary theoretical approaches to evolutionary ecology with some fundamental results in the theory of measure-valued stochastic processes allows for the development of a rigorous, yet flexible approach to synthesizing the dynamics of abundance and distributions of quantitative characters, in agreement with Champagnat, Ferrière, and Méléard (2006). Although this approach enjoys these important merits, there remains biological details and their associated technical challenges that need to be confronted for gaining a more thorough and accurate understanding of ecological communities. We touch on just four of them here and provide suggestions for future research to approach these challenges. For the first three, we recommend the use of individual-based simulations of measure-valued processes to confront these challenges. To summarize why, we state here that analytical results become difficult to derive for small populations and complicated models of mutation and selection.

Limitations of diffusion limits and generalizing coexistence theory

As noted by Feller (1951), diffusion limits provide reasonable approximations for large populations, but relatively small populations require discrete models. Hence, as a diffusion limit, SPDE (29) restricts parameter values to regions that maintain large population sizes. Although this suggests an important restriction on any model developed under this framework by implying populations are not at risk of extinction, the SDE describing abundance dynamics technically permits extinction. However, for small abundances, pathology emerges in the evolution of trait means and variances. In particular, stochastic components of the SDE describing the evolution of \bar{x} and σ^2 diverge towards infinite values as $N \rightarrow 0$. Hence, studies involving extinction and phenotypic evolution should be pursued through a different approach. A natural alternative can be developed utilizing the underlying measure-valued branching process that SAGA is a diffusion limit of (see section 2.2.3). This process explicitly tracks individuals throughout their life-history and captures reproduction as branching events. Hence, branching processes model population size as a non-negative integer instead of a continuously varying number. In particular, the pathological behavior described for the SDE of \bar{x} and σ^2 does not occur for measure-valued branching processes. This concern relates to our comment in §3.3 on using our model of diffuse coevolution to extend modern coexistence theory (sensu Chesson 2000) in a way that accounts for phenotypic evolution and demographic stochasticity. Just as previous work has sought to understand the implications of processes for coexistence separately, it seems necessary to determine whether or not results pertaining to the coexistence of competing populations hold using models that account for phenotypic evolution and demographic stochasticity simultaneously. Because such investigations consider both extinction and phenotypic evolution we argue the models used should be either simulations of, or whenever possible, analytical results based on measure-valued branching processes.

The genetic architecture and distributions of traits

Our treatment of inheritance and our approach to model coevolution rests on the assumptions of normally distributed breeding values and expressed phenotypes along with asexual reproduction. However, real traits are not encoded by an infinite number of loci each contributing an additive infinitesimal effect (as required by the infinitesimal model), mutations are not inherited as normally distributed deviations from parental breeding values (as required by the Gaussian allelic model) and many populations of interest exhibit non-random sexual reproduction. Departures from this model of genetic architecture can produce more complex distributions of breeding values and expressed traits. Such deviations can be reinforced via strong non-Gaussian selection surfaces, including the surface $m(\nu, x)$ we have derived from niche theory, along with non-

random mating in sexually reproducing populations. However, Gaussian approximations are convenient since they are defined by their mean and variance. Future work investigating the effects of non-normally distributed traits on the structure and dynamics of ecological communities will therefore need to confront higher moments such as skew and kurtosis, ideally integrating previously established mathematical approaches to derive the dynamics of these higher moments (Débarre, Yeaman, and Guillaume 2015).

Another approach to breaking the assumption of normally distributed trait values is the development of explicit multilocus models. These models describe the contributions of alleles at particular loci in the genome to the development of quantitative traits. Tracking the fluctuations of allele frequencies then allows theoreticians to investigate the dynamics of phenotypic distributions that deviate from normality. This approach has a long history in theoretical quantitative genetics (Bulmer 1980; Turelli and Barton 1994; Kirkpatrick, Johnson, and Barton 2002) and coevolutionary theory (Nuismer, Doebeli, and Browning 2005; Kopp and Gavrillets 2006; Nuismer, Ridenhour, and Oswald 2007). However, work to investigate the role of complex genetic architectures in mediating feedbacks between the dynamics of population abundances and the distributions of traits mediating ecological interactions has apparently only just begun (Patel and Bürger 2019). Since analytical results are difficult to obtain for general models of mutation, development and selection (c.f., Bürger 2000), we again suggest the use of measure-valued branching processes and their individual-based simulations. For example, by assuming the mutational effects in the BBM model is Gaussian with variance an order of magnitude greater than the equilibrium phenotypic (or genetic) variance, we obtain the so-called *House-of-cards* model (Turelli 1984). However, perhaps considering heavy-tailed distributions, such as the Laplace-distributions considered in Park et. al. (2017), will provide more realistic, yet less analytically tractable models of mutational effects. Such models have important implications in conservation genetics where small populations may evolve primarily in response to mutation and random genetic drift (Lande 1995).

Ecological stoichiometry

Our treatment of both biotic and abiotic selection neglects important chemical constraints of biological reality. For instance, the resource we assume species are competing over is modelled as a static quantity. However, real resources can be dynamic quantities. Such theoretical quantities may reflect abiotic cycles of material and energy or whole trophic layers comprised of prey, hosts or mutualists. Although resource dynamics have been captured theoretically in consumer-resource models (Tilman 1982), developing a more realistic model of resource competition must incorporate details on the ecophysiology of organisms (Loreau 2010). Doing so will help clarify the feedback between the evolution of populations and the ecosystem processes they are a part of.

Using plant-pollinator communities as an example, the role of nitrogen mediating interspecific interactions has been reviewed by David, Storkey and Stevens (2019) and the evolutionary ecology of the nutritional content of nectar has been reviewed by Parachnowitsch, Manson and Sletvold (2018). These studies demonstrate the need for further research to understand how soil nutrient availability and organismal ecophysiology structures communities of plants and pollinators. Theoretical pursuits in this direction may profit from interfacing the framework we have outlined here with population-ecosystem models such as that developed by Fridley (2017). However, these population-ecosystem models will likely yield complicated fitness functions that are difficult to analyze using rigorous mathematical techniques. Hence, we again recommend the use of simulations of measure-valued branching processes that generalize BBM to understand when analytical approximations hold.

Accounting for macroevolutionary history

To understand patterns found in ecological communities, considerations must push beyond microevolutionary and contemporary ecological processes and consider the macroevolutionary dynamics of ancestral lineages leading to extant populations. Using sub-alpine flower communities as an example, one can observe a very strict ordering of phenology across a broad geographic range. In particular, whether in the Colorado Rocky mountains (such as Gothic, Colorado) or on an outlier of the Idaho batholith (such as Kamiak butte near Palouse, Washington), one will almost surely observe a very conspicuous order of flowers emerging in early spring: at the very beginning of the season blooms *Claytonia lanceolata* followed by *Erythronium grandiflorum* which precedes *Delphinium nuttallianum* (B. Week, personal observations). If contemporary

phenological coevolution is rampant, why should this pattern be so well preserved across a thousand miles of rugged and diverse terrain? Although it would be exciting to find that these species repeatedly coevolved this pattern in each location, a more parsimonious hypothesis suggests the phenology and physiology of these species slowly evolved independently over macroevolutionary time scales to take advantage of the specific conditions available within each of these windows of the flowering season. However, this could not have carried out in the Rocky mountains since this terrain only became habitable just over ten thousand years ago as the glaciers of the Pleistocene began to retreat (Paul CaraDonna, personal communications). Hence, given these considerations, it appears that an understanding of early season phenology patterns should focus on how these communities are assembled as opposed to contemporary evolutionary dynamics. Indeed, recent work testing models of phylogeography ignores the potential for contemporary evolution and instead suggests alpine flower communities tend to follow neutral assembly where flowers merely compete for who can disperse to new habitat first, as opposed to a selective process where a regional species pool is filtered for those species adapted to the newly available habitat (Marx et al. 2017).

Of course microevolutionary and ecological dynamics are not completely irrelevant for understanding patterns in communities that are primarily structured by deep evolutionary processes. In particular, macroevolutionary trait evolution is simply the aggregation of microevolutionary change occurring over large spans of time. This suggests a road forward to connect the theory we have introduced to models of macroevolutionary trait evolution.

Some approaches to modelling macroevolutionary trait change simply repurpose microevolutionary models by blindly rescaling time from the units of generations to millions of years [Nuismer and Harmon (2014); Luke, can you think of others?]. Such an approach makes the implicit assumption that trait evolution is statistically self-similar (sensu Falconer 2014) so that the stochastic evolution of traits on macroevolutionary time scales has the same properties of trait evolution on microevolutionary time scales. Although some stochastic processes, including Brownian motion, do exhibit self-similarity, others do not. For example, consider a modification of the Ornstein-Uhlenbeck process defined by the SDE

$$dX_t = a(\theta_t - X_t)dt + bdW_t \quad (60)$$

where $a, b > 0$, W_t is a standard Brownian motion and θ_t is itself a Markov process that takes normally distributed jumps centered on its current location at exponentially distributed time intervals. If we assume the rate λ at which jumps occur is much smaller than a and the variance in jumping is much larger than b^2 , then, even though the sample paths of X_t are actually continuous (if we zoom in close enough, they look like Brownian motion), over long intervals of time sample paths of X_t will begin to appear to have periods of continuity interrupted by an occasional discontinuous jump and thus approach a qualitatively distinct process. These emergent properties can be formally characterized by Lévy processes and have been successfully employed in comparative phylogenetics to fit phenotypic data from extant populations and the fossil record (Landis and Schraiber 2017). It would therefore be interesting to investigate whether an application of a separation of time scales argument for the rate of environmental change (λ) versus the rate of evolutionary and ecological change (a) to microevolutionary models derived using our framework can be used to obtain macroevolutionary models that include not only mean trait evolution, but also the evolution of trait variance and abundance. The resulting macroevolutionary models can give rise to novel comparative phylogenetic methods and provide initial conditions for microevolutionary models that capture contemporary dynamics.

Final remarks

Although top-down approaches to community ecology, such as the Maximum Entropy Theory of Ecology (Harte 2011), have enjoyed some success in describing community-level patterns (Harte and Newman 2014; Xiao, McGlinn, and White 2015), a mechanistic understanding of why these patterns emerge and how they will change remains a formidable task. Such an understanding must take both bottom-up and top-down approaches integrating considerations from the ecophysiology of individual organisms that reveal the economics of interspecific interactions (Sternler and Elser 2008), to the phylogeographic history of taxa that sets the stage for contemporary dynamics (Hickerson et al. 2010). Through connecting these dots we can increase the variance explained in observations of ecological communities by specific mechanisms and come

1030 closer to a predictive theory of evolutionary community ecology. Despite the long list of equations derived
1031 in this paper, this work takes just one small step towards capturing these many details. However, we hope
1032 the theoretical framework outlined here along with the demonstration of its use in modelling competitive
1033 communities provides some helpful tools to aid quantitative evolutionary ecologists in reaching such lofty
1034 goals.

5 Supplementary material (SM)

Throughout this supplement, we set use dot notation for time derivatives so that $\dot{f}(x, t) = \frac{\partial}{\partial t} f(x, t)$ and set $\Delta = \sum_{i=1}^d \frac{\partial^2}{\partial x_i^2}$ the Laplace operator on \mathbb{R}^d , except in §5.12.1.3 where Δ represents a random variable.

5.1 Existence, uniqueness and regularity of solution to deterministic PDE (7) of the main text

Here we show that solutions to the PDE described in the main text exist, are unique and are twice continuously differentiable with respect to space. Our approach is an adaptation of that taken in chapter 9 §2.2 of Volpert (2014).

Recall that the PDE we consider is of the form

$$\begin{aligned} \dot{\nu}(x, t) &= m(\nu, x)\nu(x, t) + \frac{\mu}{2}\Delta\nu(x, t), \\ \nu(x, 0) &= u(x), \end{aligned} \tag{61}$$

where $m(\nu, x) \leq r \in \mathbb{R}$ is shorthand for $m((K\nu)(x, t), x)$ and $(K\nu)(x, t) = \int_{\mathbb{R}} \kappa(x - y)\nu(y, t)dy$ for some non-negative, bounded κ . Denoting $C(\mathbb{R})$ the set of continuous functions on \mathbb{R} and $L^1(\mathbb{R})$ the Lebesgue space of integrable functions on \mathbb{R} (ie, the set of functions $f : \mathbb{R} \rightarrow \mathbb{R}$ that satisfy $\|f\|_1 = \int_{\mathbb{R}} |f(x)|dx < +\infty$ under the equivalence relation $f = g$ iff $\|f - g\|_1 = 0$), we assume a continuous and integrable initial condition $\nu(\cdot, 0) = u \in L^1(\mathbb{R}) \cap C(\mathbb{R})$. We now prove the existence and uniqueness of solutions to this Cauchy problem.

Set

$$\Phi(x, t) = \frac{\exp(-x^2/2\mu t)}{\sqrt{2\pi\mu t}}. \tag{62}$$

Then the semigroup $\{S(t)\}_{t \geq 0}$ given by

$$S(t)v = \begin{cases} \int_0^t \frac{\mu}{2}\Delta\nu(x, s)ds = \int_{\mathbb{R}} \Phi(x - y, t)v(y)dy, & t > 0 \\ v, & t = 0 \end{cases} \tag{63}$$

for all $v \in L^\infty(\mathbb{R})$ satisfies $\|S(t)v\|_1 = \|v\|_1$ for all $t \geq 0$ and $v \in L^1(\mathbb{R})$. We also define the operator

$$(Fv)(x) = m\left(\int_{\mathbb{R}} \kappa(x - y)v(y)dy, x\right)v(x), \quad \forall v \in L^1(\mathbb{R}). \tag{64}$$

Thus $\|Fv\|_1 \leq |r| \|v\|_1$ for all $v \in L^1(\mathbb{R})$. Then, for any $v, w \in L^1(\mathbb{R})$,

$$\begin{aligned} Fv - Fw &= F(v + w) - F(v + w) + Fv - Fw \\ &= m(v + w, x)(v + w) - m(w, x)w - m(v + w, x)(v + w) + m(v, x)v \\ &= \left(m(v + w, x) - m(w, x)\right)w - \left(m(v + w, x) - m(v, x)\right)v + m(v + w, x)(v - w). \end{aligned} \tag{65}$$

Hence $\|Fv - Fw\|_1 \leq 2|r|(\|w\|_1 + \|v\|_2) + |r|\|v - w\|_1 \leq \|r\|\|v - w\|_1$ which implies F is Lipschitz continuous on $L^1(\mathbb{R})$. For $T > 0$ set $L^{\infty,1}([0, T] \times \mathbb{R})$ as the set of functions $\nu : [0, T] \rightarrow L^1(\mathbb{R})$ that satisfy $\|\nu\|_{1,T} = \sup_{t \in [0, T]} \|\nu(t)\|_1 < +\infty$ and consider the operator G defined on $L^{\infty,1}([0, T] \times \mathbb{R})$ for fixed $u \in L^1(\mathbb{R})$ by

$$(Gv)(t) = S(t)u + \int_0^t S(t - s)(Fv(s))ds \quad \forall t \in [0, T]. \tag{66}$$

Then for any $t \in [0, T]$ and $\nu_1, \nu_2 \in L^{\infty,1}([0, T] \times \mathbb{R})$,

$$\begin{aligned} \|G\nu_1 - G\nu_2\|_{1,T} &= \sup_{t \in [0,T]} \left\| \int_0^t S(t-s)(F\nu_1(s) - F\nu_2(s))ds \right\|_1 \\ &\leq \sup_{t \in [0,T]} t|r|\|\nu_1(t) - \nu_2(t)\|_1 \leq T|r|\|\nu_1 - \nu_2\|_{1,T}. \end{aligned} \quad (67)$$

Hence, when $T < \frac{1}{|r|}$ the operator G is a contraction operator. In this case we apply Banach's fixed point theorem to demonstrate G has a unique fixed point. That is, there exists a unique $\nu \in L^{\infty,1}([0, T] \times \mathbb{R})$ such that $G\nu = \nu$. Then, for $\nu = \nu(x, t)$ and considering $\nu(t)$ the function $x \rightarrow \nu(x, t)$, we have by definition ν is the mild solution of PDE (61) with initial condition $\nu(0) = u$. To extend this to arbitrarily large T we take a similar approach as Evans (2010) and choose $T_1 < \frac{1}{|r|}$ and apply the above argument to the interval $[T_1, 2T_1]$. Repeating this task a finite number of times shows ν is the mild solution of PDE (61) with initial condition $\nu(0) = u$ for arbitrarily large $T > 0$.

We shift our focus to showing mild solutions ν to PDE (61) are twice differentiable in x and hence are classical solutions. Applying lemma 3.3.2 of Henry (1981) we have that the mild solution ν is in fact a strong solution (i.e., differentiable with respect to $t \in (0, T)$) to the abstract Cauchy problem defined by PDE (61) with initial condition $\nu(0) = u$ for $t \in [0, T]$. In particular, this implies that $\nu(t) \in D(\Delta)$ for each $t \in (0, T)$ where $D(\Delta) = W^{2,1}(\mathbb{R})$ is the Sobolov space of integrable functions with weak derivatives at least of order 2. Since $\frac{1}{p} \geq \frac{1}{p+1} \geq \frac{1}{p} - 2$ for all $p \geq 1$, the Sobolov embedding theorem (Henry 1981) implies $D(\Delta) \subset L^p(\mathbb{R})$, the Lebesgue space of p -integrable functions on \mathbb{R} , for all $p \geq 1$. Hence $D(\Delta) \subset W^{2,p}(\mathbb{R})$, the Sobolov space of p -integrable functions with weak derivatives at least of order 2, for all $p \geq 1$.

If $v \in C^{2+\delta}(\mathbb{R})$ for some $\delta > 0$, then

$$(Kv)(\cdot) = \int_{\mathbb{R}} \kappa(\cdot - y)v(y)dy = \int_{\mathbb{R}} \kappa(y)v(\cdot - y)dy \in C^{2+\delta}(\mathbb{R}), \quad (68)$$

and, since we assume $m(h, x)$ is continuous in both arguments, $Fv = m(Kv, \cdot)v \in C^\delta$.

Why is $Fv \in C^\delta(\mathbb{R})$ for some $\delta > 0$? Why does this imply $\nu(\cdot, t) \in C^{2+\delta}(\mathbb{R})$ for all $t \in (0, T)$? This argument holds for all $T > 0$. Hence, solutions to the Cauchy problem (61) are twice continuously differentiable in their spatial parameter for all $t > 0$.

5.2 Sufficient conditions for finite mean, variance and total abundance in the deterministic case

Recall that $m(\nu, x)$ is shorthand for $m((K\nu)(x, t), x)$. That is, $m : [0, +\infty) \times \mathbb{R} \rightarrow \mathbb{R}$. Following our assumptions of the main text, we have that $m(h, x)$ is differentiable with respect to both x and h and there exists $r \in \mathbb{R}$ such that $m(h, x) \leq r$ across all $h \geq 0$ and $x \in \mathbb{R}$. As in the main text, we also assume the initial condition $\nu(x, 0)$ is continuous in x and satisfies

$$N(0) = \int_{\mathbb{R}} \nu(x, 0)dx < +\infty, \quad (69)$$

$$-\infty < \bar{x}(0) = \int_{\mathbb{R}} xp(x, 0)dx < +\infty, \quad (70)$$

$$\sigma^2(0) = \int_{\mathbb{R}} (x - \bar{x}(0))^2 p(x, 0)dx < +\infty, \quad (71)$$

where $p(x, 0) = \nu(x, 0)/N(0)$, and we consider the PDE

$$\dot{\nu}(x, t) = m(\nu, x)\nu(x, t) + \frac{\mu}{2}\Delta\nu(x, t). \quad (72)$$

In SM §5.1 we have shown PDE (72) with an integrable initial condition has a classical solution. Replacing m with its upper bound $r \in \mathbb{R}$, equation (72) reduces to a simple parabolic equation that can be solved using standard techniques (Farlow 1993). In particular, when $m(\nu, x) \equiv 0$ denote the solution to (72) by $\nu_0(x, t)$. Then, denoting

$$\Phi(x, t) = \frac{\exp(-x^2/2\mu t)}{\sqrt{2\pi\mu t}}, \quad (73)$$

we have

$$\nu_0(x, t) = \int_{\mathbb{R}} \Phi(x - y, t) \nu(y, 0) dy. \quad (74)$$

In the more general case, when $m(\nu, x) \equiv r \in \mathbb{R}$, equation (72) has the solution $\nu_r(x, t) = e^{rt} \nu_0(x, t)$. Hence, $\nu_r(x, t) \geq 0$ for all $x \in \mathbb{R}$ and $\int_{\mathbb{R}} \nu_r(x, t) dx = e^{rt} N(0) < +\infty$ for all $t \geq 0$. Furthermore, denoting

$$\begin{aligned} N_r(t) &= \int_{\mathbb{R}} \nu_r(x, t) dx, \\ p_r(x, t) &= \nu_r(x, t) / N_r(t), \\ \bar{x}_r(t) &= \int_{\mathbb{R}} x p_r(x, t) dx, \\ \sigma_r^2(t) &= \int_{\mathbb{R}} (x - \bar{x}_r(t))^2 p_r(x, t) dx, \end{aligned} \quad (75)$$

we have

$$\bar{x}_r(t) = \int_{\mathbb{R}} x \int_{\mathbb{R}} \Phi(x - y, t) p(y, 0) dy dx = \int_{\mathbb{R}} y p(y, 0) dy = \bar{x}(0), \quad (76)$$

$$\sigma_r^2(t) = \int_{\mathbb{R}} (x - \bar{x}_r(t))^2 \int_{\mathbb{R}} \Phi(x - y, t) p(y, 0) dy dx = \int_{\mathbb{R}} ((y - \bar{x}(0))^2 + \mu t) p(y, 0) dy = \sigma^2(0) + \mu t. \quad (77)$$

Hence, $|\bar{x}_r(t)|, \sigma_r^2(t) < +\infty$ for all $t \geq 0$. For the sake of contradiction, suppose there exists $x \in \mathbb{R}$ and $t \geq 0$ such that $\nu(x, t) > \nu_r(x, t)$. Then

$$\nu(x, t) - \nu(x, 0) = \int_0^t m(\nu, x) \nu(x, s) ds + \frac{\mu}{2} \Delta \nu(x, s) ds > \int_0^t r \nu_r(x, s) ds + \frac{\mu}{2} \Delta \nu_r(x, s) ds = \nu_r(x, t) - \nu(x, 0) \quad (78)$$

which implies there exists $h \geq 0$ and $x \in \mathbb{R}$ such that $m(h, x) > r$. But this contradicts our assumption $m(h, x) \leq r$ for all $h \geq 0$ and $x \in \mathbb{R}$. So we have $\nu(x, t) \leq \nu_r(x, t)$ for each $x \in \mathbb{R}$ and $t \geq 0$. This implies that $N(t) = \int_{\mathbb{R}} \nu(x, t) dx < +\infty$,

$$0 \leq \int_{\mathbb{R}} x^2 \nu(x, t) dx \leq \int_{\mathbb{R}} x^2 \nu_r(x, t) dx < +\infty \quad (79)$$

and in particular

$$0 \leq \sigma^2(t) + \bar{x}^2(t) = \frac{1}{N(t)} \int_{\mathbb{R}} x^2 \nu(x, t) dx < +\infty \quad (80)$$

for each $t \geq 0$.

5.3 The relation between diffusion and convolution with a Gaussian kernel

For continuous $g : \mathbb{R}^d \rightarrow \mathbb{R}$, consider the deterministic Cauchy problem

$$\begin{cases} \dot{f}(x, t) = \Delta f(x, t), & (x, t) \in \mathbb{R}^d \times (0, \infty) \\ f(x, t) = g(x), & (x, t) \in \mathbb{R}^d \times \{0\}. \end{cases} \quad (81)$$

According to Evans (2010), the fundamental solution of (81) is

$$\Phi(x, t) = \frac{1}{(4\pi t)^{d/2}} \exp\left(-\frac{|x|^2}{4t}\right), \quad (x, t) \in (0, \infty) \times \mathbb{R}^d, \quad (82)$$

where $|x| = \sqrt{\sum_i x_i^2}$. The solution $f(x, t)$ of PDE (81) is then given by the convolution

$$f(x, t) = \int_{\mathbb{R}^d} \Phi(x - y, t) g(y) dy, \quad (x, t) \in (0, \infty) \times \mathbb{R}^d. \quad (83)$$

1105 Hence, by the fundamental theorem of calculus,

$$\begin{aligned}
 f(x, t) + \int_t^{t+1} \dot{f}(x, s) ds &= f(x, t+1) \\
 &= \int_{\mathbb{R}^d} \Phi(x-y, t+1) g(y) dy = \int_{\mathbb{R}^d} \int_{\mathbb{R}^d} \Phi(x-y, 1) \Phi(y-z, t) g(z) dz dy \\
 &= \int_{\mathbb{R}^d} \Phi(x-y, 1) f(t, y) dy. \quad (84)
 \end{aligned}$$

1106 In particular,

$$f(x, t) + \int_t^{t+1} \Delta f(x, s) ds = \int_{\mathbb{R}^d} \Phi(1, x-y) f(y, t) dy. \quad (85)$$

1107 5.4 Equilibrium moments for a deterministic population experiencing logistic 1108 growth and stabilizing selection

1109 Here we set out to show, given the initial conditions $\nu(\cdot, 0) \in L^1(\mathbb{R})$ such that $\bar{x}(0) \in \mathbb{R}$, $\sigma^2(0) \in [0, +\infty)$
1110 and $N(0) \in (0, +\infty)$, and given the growth rate

$$m(\nu, x) = r - \frac{a}{2}(\theta - x)^2 - c \int_{\mathbb{R}} \nu(y, t) dy \quad (86)$$

1111 such that $\theta \in \mathbb{R}$, $a, c, \mu > 0$ and $r > \frac{1}{2}\sqrt{\mu a}$, we have the following stable equilibrium $N_\infty = \lim_{t \rightarrow \infty} N(t) =$
1112 $\frac{1}{c}(r - \frac{1}{2}\sqrt{a\mu})$, $\bar{x}_\infty = \lim_{t \rightarrow \infty} \bar{x}(t) = \theta$ and $\sigma_\infty^2 = \lim_{t \rightarrow \infty} \sigma^2(t) = \sqrt{\frac{\mu}{a}}$.

1113 The mean fitness can be calculated as

$$\bar{m}(t) = r - \frac{a}{2}((\theta - \bar{x}(t))^2 + \sigma^2(t)) - cN(t). \quad (87)$$

1114 Recalling the ODE derived for $N(t)$,

$$\frac{d}{dt}N(t) = \bar{m}(t)N(t) = (r - \frac{a}{2}((\theta - \bar{x}(t))^2 + \sigma^2(t)) - cN(t))N(t), \quad (88)$$

1115 solving for equilibrium total abundance \hat{N} amounts to setting $\frac{d}{dt}N(t) = 0$ and solving for $N(t)$. Ignoring the
1116 equilibrium $N(t) = 0$, this reduces to solving $\bar{m}(t) = 0$ for $N(t)$, which returns

$$\hat{N} = \frac{1}{c} \left(r - \frac{a}{2}((\theta - \hat{x})^2 - \hat{\sigma}^2) \right). \quad (89)$$

1117 Unfortunately, deriving ODE for $\bar{x}(t)$ and $\sigma^2(t)$ leads to expressions involving higher moments and finding
1118 ODE for these higher moments will lead to expressions involving yet even higher moments. To avoid this
1119 infinite regression, we find the equilibrium abundance density $\hat{\nu}(x)$ by solving $\frac{\partial}{\partial t}\nu(x, t) = 0$ for $\nu(x, t)$. This
1120 implies the following ordinary differential equation

$$\frac{d^2}{dx^2}\hat{\nu}(x) = \left(\frac{2c}{\mu}\hat{N} + \frac{a}{\mu}(\theta - x)^2 - \frac{2r}{\mu} \right) \hat{\nu}(x) \quad (90)$$

1121 which has the solution

$$\hat{\nu}(x) = \frac{\hat{N}}{\sqrt{2\pi}} \left(\frac{a}{\mu} \right)^{\frac{1}{4}} \exp \left(-\sqrt{\frac{a}{\mu}} \frac{(\theta - x)^2}{2} \right). \quad (91)$$

1122 From this expression we infer $\hat{x} = \theta$ and $\hat{\sigma}^2 = \sqrt{\frac{\mu}{a}}$. Hence $\hat{N} = \frac{1}{c} \left(r - \frac{1}{2}\sqrt{a\mu} \right)$. To show that $N_\infty = \hat{N}$,
1123 $\bar{x}_\infty = \hat{x}$ and $\sigma_\infty^2 = \hat{\sigma}^2$, we linearize ODE for $N(t)$, $\bar{x}(t)$ and $\sigma^2(t)$ using the equilibrium $\hat{\nu}(x)$. In particular,
1124 since $\hat{\nu}(x)$ is Gaussian, we do not run into the same issue with higher moments as above. Assuming the

equilibrium $\hat{\nu}(x)$ does not change the ODE for $N(t)$, but the ODE for $\bar{x}(t)$ and $\sigma^2(t)$ can now be expressed as

$$\frac{d}{dt}\bar{x}(t) = \sigma^2(t) \left(\frac{\partial \bar{m}(t)}{\partial \bar{x}(t)} - \overline{\frac{\partial m(t)}{\partial \bar{x}(t)}} \right) = a\sigma^2(t)(\theta - \bar{x}(t)), \quad (92)$$

$$\frac{d}{dt}\sigma^2(t) = 2\sigma^4(t) \left(\frac{\partial \bar{m}(t)}{\partial \sigma^2(t)} - \overline{\frac{\partial m(t)}{\partial \sigma^2(t)}} \right) + \mu = \mu - a\sigma^4(t), \quad (93)$$

where $\hat{p}(x) = \hat{\nu}(x)/\hat{N}$. These expressions confirm our findings that $\hat{\bar{x}} = \theta$ and $\hat{\sigma}^2 = \sqrt{\frac{\mu}{a}}$. Furthermore, calculating

$$\frac{\partial}{\partial \sigma^2(t)} \frac{d}{dt}\sigma^2(t) = -2a\sigma^2(t) \quad (94)$$

and evaluating at $\sigma^2(t) = \hat{\sigma}^2$ demonstrates the equilibrium phenotypic variance is stable when $a, \mu > 0$. Hence, calculating

$$\frac{\partial}{\partial \bar{x}(t)} \frac{d}{dt}\bar{x}(t) = -a\sigma^2(t) \quad (95)$$

and evaluating at $\sigma^2(t) = \hat{\sigma}^2$ and $\bar{x}(t) = \hat{\bar{x}}$ demonstrates the equilibrium phenotypic mean is stable when $a, \mu > 0$. Finally, calculating

$$\frac{\partial}{\partial N(t)} \frac{d}{dt}N(t) = r - \frac{a}{2}((\theta - \bar{x}(t))^2 + \sigma^2(t)) - 2cN(t) \quad (96)$$

and evaluating at $\sigma^2(t) = \hat{\sigma}^2$, $\bar{x}(t) = \hat{\bar{x}}$ and $N(t) = \hat{N}$ demonstrates the equilibrium total abundance is stable when $a, c, \mu > 0$, and $r > \frac{1}{2}\sqrt{a\mu}$.

5.5 Deterministic dynamics of $\sigma^2(t)$

Picking up from the main text §2.1,

$$\begin{aligned} \frac{d}{dt}\sigma^2(t) &= \frac{d}{dt} \int_{\mathbb{R}} (x - \bar{x}(t))^2 p(x, t) dx = \int_{\mathbb{R}} 2(x - \bar{x}(t)) \frac{d}{dt}\bar{x}(t) + (x - \bar{x}(t))^2 \frac{\partial}{\partial t} p(x, t) dx \\ &= \int_{\mathbb{R}} (x - \bar{x}(t))^2 \left((m(\nu, x) - \bar{m}(t)) p(x, t) + \frac{\mu}{2} \frac{\partial^2}{\partial x^2} p(x, t) \right) dx \\ &= \int_{\mathbb{R}} ((x - \bar{x}(t))^2 - \sigma^2(t) + \sigma^2(t)) (m(\nu, x) - \bar{m}(t)) p(x, t) + (x - \bar{x}(t))^2 \frac{\mu}{2} \frac{\partial^2}{\partial x^2} p(x, t) dx \\ &= \text{Cov}_t \left((x - \bar{x}(t))^2, m(\nu, x) \right) + \frac{\mu}{2} \int_{\mathbb{R}} (x - \bar{x}(t))^2 \frac{\partial^2}{\partial x^2} p(x, t) dx. \end{aligned} \quad (97)$$

Applying integration by parts twice yields

$$\int_{-\infty}^{+\infty} (x - \bar{x}(t))^2 \frac{\partial^2}{\partial x^2} p(x, t) dx = 2. \quad (98)$$

5.6 Simplifying covariances with fitness under the assumption of a Gaussian density

By assuming

$$p(x, t) = \frac{\exp\left(-\frac{(x - \bar{x}(t))^2}{2\sigma^2(t)}\right)}{\sqrt{2\pi\sigma^2(t)}} \quad (99)$$

1142 we have

$$\begin{aligned}
\sigma^2 \left(\frac{\partial \bar{m}}{\partial \bar{x}} - \overline{\frac{\partial m}{\partial \bar{x}}} \right) &= \sigma^2 \left(\frac{\partial}{\partial \bar{x}} \int_{\mathbb{R}} m(\nu, x) p(x, t) dx - \int_{\mathbb{R}} p(x, t) \frac{\partial}{\partial \bar{x}} m(\nu, x) dx \right) \\
&= \sigma^2 \int_{\mathbb{R}} m(\nu, x) \frac{\partial}{\partial \bar{x}} p(x, t) dx = \sigma^2 \int_{\mathbb{R}} \frac{x - \bar{x}(t)}{\sigma^2} m(\nu, x) p(x, t) dx \\
&= \int_{\mathbb{R}} (x - \bar{x})(m(\nu, x) - \bar{m}) p(x, t) dx = \text{Cov}_t(m, x), \quad (100)
\end{aligned}$$

1143 and

$$\begin{aligned}
2\sigma^4 \left(\frac{\partial \bar{m}}{\partial \sigma^2} - \overline{\frac{\partial m}{\partial \sigma^2}} \right) &= 2\sigma^4 \left(\frac{\partial}{\partial \sigma^2} \int_{\mathbb{R}} m(\nu, x) p(x, t) dx - \int_{\mathbb{R}} p(x, t) \frac{\partial}{\partial \sigma^2} m(\nu, x) dx \right) \\
&= 2\sigma^4 \int_{\mathbb{R}} \frac{(x - \bar{x})^2 - \sigma^2}{2\sigma^4} m(\nu, x) p(x, t) dx = \int_{\mathbb{R}} ((x - \bar{x})^2 - \sigma^2) (m(\nu, x) - \bar{m}) p(x, t) dx \\
&= \text{Cov}_t((x - \bar{x})^2, m). \quad (101)
\end{aligned}$$

1144 5.7 Comparing our treatment of white noise to Da Prato and Zabczyk (2014)

1145 Our approach in the main text is inspired by the treatment provided in §4.2 of Da Prato and Zabczyk
1146 (2014). Here the authors develop a stochastic integral of operator-valued processes. In particular, they
1147 consider processes indexed by time $t \geq 0$ valued as Hilbert-Schmidt operators $\Phi(t)$ and define the norm

$$\|\Phi\|_t = \sqrt{\mathbb{E} \left(\int_0^t \text{Tr}[\Phi(s)\Phi^*(s)] ds \right)}, \quad t \geq 0. \quad (102)$$

1148 In our case we only consider the so-called multiplication operators. That is, processes that consist of operators
1149 $\Phi(t)$ having the form $\Phi(t)g(x) = \varphi(x, t)g(x)$ such that $\varphi(\cdot, t) \in L^2(\mathbb{R})$ a.s. for each $t \geq 0$. In this case
1150 $\Phi(t) = \Phi^*(t)$ and

$$\|\Phi\|_t = \|\varphi\|_t = \sqrt{\mathbb{E} \left(\int_0^t \int_{\mathbb{R}} \varphi^2(x, s) dx ds \right)}, \quad t \geq 0. \quad (103)$$

1151 Da Prato and Zabczyk (2014) form the space $\mathcal{N}_W^2(0, T)$ of Hilbert-Schmidt operator-valued predictable
1152 processes $\Phi(t)$ that satisfy $\|\Phi\|_T < +\infty$ for some $T > 0$. This corresponds to our more specialized space \mathcal{N}_2
1153 that consists of $L^2(\mathbb{R})$ valued processes $\varphi(x, t)$ such that $\|\varphi\|_t < +\infty$ for all $t \geq 0$. In their treatment, $W(t)$
1154 plays a similar role to our generalized process \mathbf{W}_t . For $\Phi \in \mathcal{N}_W^2(0, T)$, they denote the stochastic integral
1155 for $t \in [0, T]$ by $\Phi \cdot W(t)$. Hence, for $\Phi(t)g(x) = \varphi(x, t)g(x)$ as above, $\mathbf{W}_t(\varphi) = \Phi \cdot W(t)$. The authors then
1156 prove the following:

1157 **Proposition 4.28** *Assume that $\Phi_1, \Phi_2 \in \mathcal{N}_W^2(0, T)$. Then*

$$\mathbb{E}(\Phi_i \cdot W(t)) = 0, \quad \mathbb{E}(\|\Phi_i \cdot W(t)\|^2) < +\infty, \quad \forall t \in [0, T].$$

1158 **Corollary 4.29** *Under the same assumptions as Proposition 4.28,*

$$\mathbb{C}(\Phi_1 \cdot W(t), \Phi_2 \cdot W(s)) = \mathbb{E} \left(\int_0^{t \wedge s} \text{Tr}[\Phi_2(r)\Phi_1^*(r)] dr \right), \quad \forall t, s \in [0, T].$$

1159 Simplifying these expressions for the multiplication operators described above returns equations (22) and
1160 (23) of the main text.

5.8 Simulating the rescaled process and numerical evidence of approximate normality

Here we use a numerical argument to suggest, for

$$r - \frac{a}{2}(\theta - x)^2 - c \int_{\mathbb{R}} \nu(x, t) dx \leq m(\nu, x) \leq r - \frac{a}{2}(\theta - x)^2, \quad \forall (\nu, x) \in C_{1,c}^+(\mathbb{R}) \times \mathbb{R}, \quad (104)$$

the density process $\nu(x, t)$ defined by SPDE (29) of the main text satisfies $\int_{\mathbb{R}} (|x| + x^2) \nu(x, t) dx < \infty$.

and setting $c < r - (\eta a + \sqrt{\mu a})/2$ ensures $\hat{N} > 1$, which is important for numerical simulations when N is an integer. We use these results to help guide our choice of parameter values for simulations of the branching random walk. In the following section we provide a detailed description of the branching random walk and how we have chosen to rescale it. We then use the rescaled branching random walk to investigate finiteness of moments and normality.

5.8.1 Description of simulation

We begin by describing the branching random walk before introducing our scheme to rescale it. Our branching random walk follows closely the description of branching Brownian motion in the main text. However, we replace exponentially distributed lifetimes with deterministic unit time steps for easier implementation. Hence, we restrict time to $t = 0, 1, 2, \dots$. Furthermore, we allow individual fitness to depend on both trait value and the state of the entire population. For time t we write $\{\xi_1(t), \dots, \xi_{N(t)}(t)\}$ as the set of trait values across all $N(t)$ individuals alive in the population. Since our simulation treats individuals instead of continuous distributions of trait values, we can write

$$\nu(x, t) = \sum_{i=1}^{N(t)} \delta(x - \xi_i(t)), \quad (105)$$

where $\delta(x - \xi_i(t))$ denotes the point mass located at $\xi_i(t)$. To allow for imperfect heritability, we also track the set of breeding values which, at time t , is denoted by $\{\gamma_1(t), \dots, \gamma_{N(t)}(t)\}$ and should not be confused with the quadratic selection gradients discussed in §5.11 of the main text. Then the distribution of breeding values can be written as

$$\rho(g, t) = \sum_{i=1}^{N(t)} \delta(g - \gamma_i(t)). \quad (106)$$

Following our model of heritability, the trait value $\xi_i(t)$ is drawn from a normal distribution centered on $\gamma_i(t)$ with variance η . At each iteration we draw, for each individual, a random number of offspring from a Negative-Binomial distribution. Recall the Negative-Binomial distribution models the number of failed Bernoulli trials that occur before a given number of successful trials. Denoting q the probability of success for each trial and s the number of successes, the mean and variance is given respectively by

$$\frac{s(1-q)}{q}, \quad \frac{s(1-q)}{q^2}. \quad (107)$$

Then if we require the i th individual to have mean number offspring $\mathcal{W}(\nu, \xi_i)$ and variance equal to V , the parameters of the associated Negative-Binomial distribution become

$$q(\nu, \xi_i) = \frac{\mathcal{W}(\nu, \xi_i)}{V}, \quad s(\nu, \xi_i) = \frac{\mathcal{W}^2(\nu, \xi_i)}{V - \mathcal{W}(\nu, \xi_i)}. \quad (108)$$

The imposes the restriction $V > \mathcal{W}(\nu, \xi_i)$. For each offspring produced by the individual with breeding value $\gamma_i(t)$, we assign indepently drawn breeding values normally distributed around $\gamma_i(t)$ with variance μ . After breeding values have been assigned, we randomly draw trait values for each offspring as described above. For an overview of our model of inheritance, see §2.3.2 of the main text. This summarizes the basic structure of our simulation. To impose selection and density dependent growth rates, we set

$$\mathcal{W}(\nu, \xi_i) = \exp \left(r - \frac{a}{2}(\theta - \xi_i)^2 - c \int_{\mathbb{R}} \nu(x, t) dx \right), \quad (109)$$

where the above integral becomes $\int_{\mathbb{R}} \nu(x, t) dx = \sum_{i=1}^{N(t)} 1 = N(t)$.

Rescaling

To rescale the branching random walk by a positive integer n , we rescale segregation and mutational variance according to $\eta \rightarrow \eta$ and $\mu \rightarrow \mu/n$, time by $t \rightarrow t/n$ and the reproductive law by $V \rightarrow V$ and

$$\mathcal{W}(\nu, \xi_i) \rightarrow \mathcal{W}^{(n)}(\nu, \xi_i) = \exp \left(\frac{r}{n} - \frac{a}{2n}(\theta - \xi_i)^2 - \frac{c}{n^2} N(t) \right) = \exp \left(\frac{r}{n} - \frac{a}{2n}(\theta - \xi_i)^2 - \frac{c}{n} N^{(n)}(t) \right). \quad (110)$$

We also replace individual mass with $\frac{1}{n}$ and write rescaled abundance as $N^{(n)}(t) = \frac{1}{n} N(nt)$. Under this rescaling the deterministic equilibrium of the raw numerical abundance becomes

$$\hat{N} = \frac{n^2}{c} \left(\frac{r}{n} - \frac{1}{2n}(\eta a + \sqrt{\mu a}) \right) = \frac{n}{c} \left(r - \frac{1}{2}(\eta a + \sqrt{\mu a}) \right). \quad (111)$$

The deterministic equilibrium of the rescaled abundance is then

$$\hat{N}^{(n)} = \frac{1}{c} \left(r - \frac{1}{2}(\eta a + \sqrt{\mu a}) \right). \quad (112)$$

When it exists, we denote by $N^{(\infty)}(t)$ the limiting process of $N^{(n)}(t)$. Then

$$\lim_{n \rightarrow \infty} n \left(\mathcal{W}^{(n)}(\nu, \xi_i) - 1 \right) = r - \frac{a}{2}(\theta - \xi_i)^2 - c N^{(\infty)}(t). \quad (113)$$

Note that, following the notation of Theorem 1 in Méléard and Roelly (1992), setting $\lambda_n = n$, $m_n(\nu) = \mathcal{W}^{(n)}(\nu, \cdot)$ and $\varepsilon_n = 1/n$ satisfies their hypotheses (\mathcal{H}_0) – (\mathcal{H}_3) when $c = 0$. We have implemented this simulation in the programming language Julia. A copy can be found at the url:

<https://github.com/bobweek/branching.brownian.motion.and.spde>

For the sake of illustration, we simulated the unscaled process ($n = 1$) and the rescaled process with $n = 5$ and $n = 20$ for 50 units of time. Results are shown in Figure 2. In the following section we use a statistical test to show, for the lower bound on $m(\nu, x)$, the rescaled process converges to a Gaussian density as $n \rightarrow \infty$ and $V/N \rightarrow 0$.

5.8.2 Evidence of normality

To demonstrate approximate normality of the phenotypic distribution when V/N is small we utilized the one-sided Kolmogorov-Smirnov test. This test compares an empirical cumulative distribution function (i.e., a cumulative distribution function generated from simulated data) to a hypothetical cumulative distribution function by providing a distribution for the maximum distance between these curves. More precisely if $F_n(x)$ is the empricial distribution function for a sample of size n and $F(x)$ is the hypothetical distribution function, Kolmogorov-Smirnov statistic is $D_n = \sup_x |F_n(x) - F(x)|$.

5.9 Derivation of SDE for \bar{x} and σ^2

Picking up from §2.2.3 of the main text, we have

$$\tilde{x}(t) = \int_{\mathbb{R}} x\nu(x, t)dx, \quad \tilde{\sigma}^2(t) = \int_{\mathbb{R}} x^2\nu(x, t)dx \quad (114)$$

and

$$\tilde{x}(t) = \tilde{x}(0) + \int_0^t \int_{\mathbb{R}} \nu(x, s)m(\nu, x)x + x\sqrt{V\nu(x, s)}\dot{W}(x, s)dx ds, \quad (115)$$

$$\tilde{\sigma}^2(t) = \tilde{\sigma}^2(0) + \int_0^t \int_{\mathbb{R}} \nu(x, s)(m(\nu, x)x^2 + \mu) + x^2\sqrt{V\nu(x, s)}\dot{W}(x, s)dx ds. \quad (116)$$

5.9.1 Derivation for trait mean

We make use of the notation

$$\begin{cases} \|N\|_2 = \sqrt{V \int_{\mathbb{R}} \nu(x, t)dx} = \sqrt{VN} \\ \|\tilde{x}\|_2 = \sqrt{V \int_{\mathbb{R}} x^2\nu(x, t)dx} \\ \langle \tilde{x}, N \rangle = V \int_{\mathbb{R}} x\nu(x, t)dx = \bar{x}VN. \end{cases} \quad (117)$$

Rewriting formula (115) as an SDE provides

$$d\tilde{x} = \left(\bar{x}mN + \frac{\mu}{2} \int_{\mathbb{R}} x\Delta\nu(x, t)dx \right) dt + \|\tilde{x}\|_2 d\tilde{W}_2, \quad (118)$$

where,

$$d\tilde{W}_2 = d\hat{\mathbf{W}}_t(\sqrt{Vx^2\nu}) = \frac{1}{\|\tilde{x}\|_2} \int_{\mathbb{R}} x\sqrt{V\nu(x, t)}\dot{W}(x, t)dx dt. \quad (119)$$

Using Itô's quotient rule on $\bar{x} = \tilde{x}/N$, we obtain

$$d\bar{x} = d\left(\frac{\tilde{x}}{N}\right) = \frac{\tilde{x}}{N} \left(\frac{d\tilde{x}}{\tilde{x}} - \frac{dN}{N} - \frac{d\tilde{x}}{\tilde{x}} \frac{dN}{N} + \left(\frac{dN}{N}\right)^2 \right) = \frac{d\tilde{x}}{N} - \bar{x} \frac{dN}{N} - \frac{d\tilde{x}}{N} \frac{dN}{N} + \bar{x} \left(\frac{dN}{N}\right)^2. \quad (120)$$

From Table 1 of the main text $d\tilde{x}dN = \langle \tilde{x}, N \rangle$ and $dN^2 = \|N\|_2^2$. Hence,

$$\begin{aligned} d\bar{x} &= \bar{x}m dt + \frac{\|\tilde{x}\|_2}{N} d\tilde{W}_2 - \bar{x} \left(\bar{m} dt + \sqrt{\frac{V}{N}} dW_1 \right) - \frac{\langle \tilde{x}, N \rangle}{N^2} dt + \bar{x} \frac{\|N\|_2^2}{N^2} dt \\ &= (\bar{x}m - \bar{x}\bar{m}) dt + \frac{\|\tilde{x}\|_2}{N} d\tilde{W}_2 - \bar{x} \sqrt{\frac{V}{N}} dW_1 - V \frac{\bar{x}}{N} dt + V \frac{\bar{x}}{N} dt \\ &= \text{Cov}_t(x, m) + \frac{\|\tilde{x}\|_2}{N} d\tilde{W}_2 - \bar{x} \sqrt{\frac{V}{N}} dW_1. \end{aligned} \quad (121)$$

Note that

$$\begin{aligned} \frac{\|\tilde{x}\|_2}{N} d\tilde{W}_2 - \bar{x} \sqrt{\frac{V}{N}} dW_1 &= \frac{1}{N} \int_{\mathbb{R}} x \sqrt{V\nu(x,t)} \dot{W}(x,t) dx - \frac{\bar{x}}{N} \int_{\mathbb{R}} \sqrt{V\nu(x,t)} \dot{W}(x,t) dx \\ &= \int_{\mathbb{R}} \frac{x - \bar{x}}{N} \sqrt{V\nu(x,t)} \dot{W}(x,t) dx \end{aligned} \quad (122)$$

1228 and

$$\mathbb{V} \left(\int_{\mathbb{R}} \frac{x - \bar{x}}{N} \sqrt{V\nu(x,t)} \dot{W}(x,t) dx \right) = \frac{V}{N} \int_{\mathbb{R}} (x - \bar{x})^2 p(x,t) dx = V \frac{\sigma^2}{N}. \quad (123)$$

1229 Hence, by setting

$$dW_2 = \frac{\int_{\mathbb{R}} \frac{(x - \bar{x})}{N} \sqrt{V\nu(x,t)} \dot{W}(x,t) dx}{\sqrt{V\sigma^2/N}} \quad (124)$$

1230 we can write

$$d\bar{x} = \text{Cov}_t(x, m) dt + \sqrt{V \frac{\sigma^2}{N}} dW_2. \quad (125)$$

1231 5.9.2 Derivation for trait variance

1232 We make use of the notation

$$\begin{cases} \|\tilde{\sigma}^2\|_2 = \sqrt{V \int_{\mathbb{R}} x^4 \nu(x,t) dx} \\ \langle \tilde{\sigma}^2, N \rangle = V \int_{\mathbb{R}} x^2 \nu(x,t) dx = \overline{x^2} V N. \end{cases} \quad (126)$$

1233 Applying formula (116) provides

$$d\tilde{\sigma}^2 = \left(\overline{x^2 m} N + \mu N \right) dt + \|\tilde{\sigma}^2\|_2 d\tilde{W}_3 \quad (127)$$

1234 where

$$d\tilde{W}_3 = d\hat{\mathbf{W}}_t(\sqrt{V x^4 \nu}) = \frac{1}{\|\tilde{\sigma}^2\|_2} \int_{\mathbb{R}} x^2 \sqrt{V\nu(x,t)} \dot{W}(x,t) dx. \quad (128)$$

1235 Using Itô's quotient rule on $\overline{x^2} = \tilde{\sigma}^2/N$, we obtain

$$d\overline{x^2} = d \left(\frac{\tilde{\sigma}^2}{N} \right) = \frac{\tilde{\sigma}^2}{N} \left(\frac{d\tilde{\sigma}^2}{\tilde{\sigma}^2} - \frac{dN}{N} - \frac{d\tilde{\sigma}^2}{\tilde{\sigma}^2} \frac{dN}{N} + \left(\frac{dN}{N} \right)^2 \right) = \frac{d\tilde{\sigma}^2}{N} - \overline{x^2} \frac{dN}{N} - \frac{d\tilde{\sigma}^2}{N} \frac{dN}{N} + \overline{x^2} \left(\frac{dN}{N} \right)^2. \quad (129)$$

1236 Table 1 of the main text implies $d\tilde{W}_3 dW_1 = \langle \tilde{\sigma}^2, N \rangle$ and hence

$$\begin{aligned}
d\bar{x}^2 &= \left(\overline{x^2 m} + \mu\right) dt + \frac{\|\tilde{\sigma}^2\|_2}{N} d\tilde{W}_3 - \bar{x}^2 \left(\bar{m} dt + \sqrt{\frac{V}{N}} dW_1\right) - \frac{\langle \tilde{\sigma}^2, N \rangle}{N^2} dt + \bar{x}^2 \frac{\|N\|_2^2}{N^2} dt \\
&= \left(\overline{x^2 m} - \bar{x}^2 \bar{m} dt + \mu\right) dt + \frac{\|\tilde{\sigma}^2\|_2}{N} d\tilde{W}_3 - \bar{x}^2 \sqrt{\frac{V}{N}} dW_1 - \bar{x}^2 \frac{V}{N} dt + \bar{x}^2 \frac{V}{N} dt \\
&= \left(\text{Cov}_t(x^2, m) + \mu\right) dt + \frac{\|\tilde{\sigma}^2\|_2}{N} d\tilde{W}_3 - \bar{x}^2 \sqrt{\frac{V}{N}} dW_1. \quad (130)
\end{aligned}$$

1237 Setting $F(y, z) = y - z^2$, use Itô's formula on $\sigma^2 = F(\bar{x}^2, \bar{x}) = \bar{x}^2 - \bar{x}^2$ to obtain:

$$\begin{aligned}
d\sigma^2 &= d\bar{x}^2 - 2\bar{x}d\bar{x} - (d\bar{x})^2 = \left(\text{Cov}_t(x^2, m) + \mu\right) dt + \frac{\|\tilde{\sigma}^2\|_2}{N} d\tilde{W}_3 - \bar{x}^2 \sqrt{\frac{V}{N}} dW_1 \\
&\quad - 2\bar{x} \left(\text{Cov}_t(x, m) + \mu dt + \sqrt{\frac{V\sigma^2}{N}} dW_2\right) - \left(\text{Cov}_t(x, m) dt + \mu dt + \sqrt{\frac{V\sigma^2}{N}} dW_2\right)^2 \\
&= \left(\text{Cov}_t(x^2 - 2\bar{x}x, m) + \mu\right) dt + \frac{\|\tilde{\sigma}^2\|_2}{N} d\tilde{W}_3 - \bar{x}^2 \sqrt{\frac{V}{N}} dW_1 - 2\bar{x} \sqrt{\frac{V\sigma^2}{N}} dW_2 - \left(\frac{V\sigma^2}{N}\right) dt \\
&= \left(\text{Cov}_t(x - \bar{x})^2, m\right) + \mu - \frac{V\sigma^2}{N} dt + \frac{\|\tilde{\sigma}^2\|_2}{N} d\tilde{W}_3 - \bar{x}^2 \sqrt{\frac{V}{N}} dW_1 - 2\bar{x} \sqrt{\frac{V\sigma^2}{N}} dW_2. \quad (131)
\end{aligned}$$

1238 In light of

$$\begin{aligned}
\frac{\|\tilde{\sigma}^2\|_2}{N} d\tilde{W}_3 - \bar{x}^2 \sqrt{\frac{V}{N}} dW_1 - 2\bar{x} \sqrt{\frac{V\sigma^2}{N}} dW_2 &= \frac{1}{N} \int_{\mathbb{R}} (x^2 - \tilde{\sigma}^2 - 2\bar{x}(x - \bar{x})) \sqrt{V\nu(x, t)} \dot{W}(x, t) dx \\
&= \frac{1}{N} \int_{\mathbb{R}} ((x - \bar{x})^2 - \sigma^2) \sqrt{V\nu(x, t)} \dot{W}(x, t) dx \quad (132)
\end{aligned}$$

1239 and

$$\begin{aligned}
\frac{1}{N} \int_{\mathbb{R}} \left(((x - \bar{x})^2 - \sigma^2) \sqrt{V\nu(x, s)} \right)^2 dx &= \frac{V}{N} \left(\int_{\mathbb{R}} ((x - \bar{x})^4 - 2(x - \bar{x})^2 \sigma^2 + \sigma^4) p(x, t) dx \right) \\
&= \frac{V}{N} \left(\overline{(x - \bar{x})^4} - \sigma^4 \right) \quad (133)
\end{aligned}$$

1240 we set

$$dW_3 = \frac{\int_{\mathbb{R}} ((x - \bar{x})^2 - \sigma^2) \sqrt{V\nu(x, t)} \dot{W}(x, t) dx}{V \left(\overline{(x - \bar{x})^4} - \sigma^4 \right)} \quad (134)$$

1241 so that

$$d\sigma^2 = \text{Cov}_t\left((x - \bar{x})^2, m\right)dt + \left(\mu - V\frac{\sigma^2}{N}\right)dt + \sqrt{V\frac{(x - \bar{x})^4 - \sigma^4}{N}}dW_3. \quad (135)$$

1242 Table 1 of the main text implies

$$dW_1dW_2 = \frac{\int_{\mathbb{R}}(x - \bar{x})\nu(x, t)dx}{\sqrt{N\sigma^2}}dt = 0, \quad (136)$$

$$dW_1dW_3 = \frac{\int_{\mathbb{R}}((x - \bar{x})^2 - \sigma^2)\nu(x, t)dx}{\sqrt{(x - \bar{x})^4 - \sigma^4}}dt = 0, \quad (137)$$

$$dW_2dW_3 = \frac{\int_{\mathbb{R}}(x - \bar{x})((x - \bar{x})^2 - \sigma^2)p(x, t)dx}{\sqrt{\sigma^2((x - \bar{x})^4 - \sigma^4)}}dt = \frac{N\overline{(x - \bar{x})^3}}{\sqrt{\sigma^2((x - \bar{x})^4 - \sigma^4)}}dt. \quad (138)$$

1243 In particular, when p is a Gaussian curve $dW_2dW_3 = 0$.

1244 5.10 Relating fitness of expressed traits to fitness of breeding values

1245 Following §2.3.2 of the main text, we have $\sigma^2 = G + \eta$ and

$$m^*(\rho, g) = \int_{\mathbb{R}} m(\nu, x)\psi(x, g)dx. \quad (139)$$

1246 Hence,

$$\begin{aligned} \overline{\frac{\partial m^*}{\partial \bar{x}}} &= \int_{\mathbb{R}} \frac{\rho(g, t)}{N(t)} \frac{\partial}{\partial \bar{x}} \int_{\mathbb{R}} m(\nu, x)\psi(x, g)dx dg = \\ &= \int_{\mathbb{R}} \int_{\mathbb{R}} \frac{\rho(g, t)}{N(t)} \psi(x, g) dg \frac{\partial}{\partial \bar{x}} m(\nu, x) dx = \int_{\mathbb{R}} p(x, t) \frac{\partial}{\partial \bar{x}} m(\nu, x) dx = \overline{\frac{\partial m}{\partial \bar{x}}} \end{aligned} \quad (140)$$

1247 and

$$\begin{aligned} \overline{\frac{\partial m^*}{\partial G}} &= \int_{\mathbb{R}} \frac{\rho(g, t)}{N(t)} \frac{\partial}{\partial G} \int_{\mathbb{R}} m(\nu, x)\psi(x, g)dx dg = \int_{\mathbb{R}} \int_{\mathbb{R}} \frac{\rho(g, t)}{N(t)} \psi(x, g) dg \frac{\partial m}{\partial G} dx = \\ &= \int_{\mathbb{R}} p(x, t) \frac{\partial m}{\partial \sigma^2} \frac{\partial \sigma^2}{\partial G} dx = \overline{\frac{\partial m}{\partial \sigma^2}}. \end{aligned} \quad (141)$$

1248 5.11 Derivation of diffuse coevolution model

1249 In this section we provide a derivation of our model of diffuse coevolution driven by competition. Since most
1250 of the work in this derivation has already been completed in Supplementary Material §5.9, we focus here
1251 on deriving the Malthusian fitness m as a function of trait value x . We begin with discrete populations of
1252 individuals. In particular, we begin by assuming population size n_i is an integer for each species $i = 1, \dots, S$
1253 before passing to the large population size limit.

The reduction in fitness for an individual of species i caused by competition is captured multiplicatively by $0 < C_i \leq 1$. Biologically this assumes all competitors affect individuals of a given species equally by consuming the same amount of resources. This is a mean-field interaction since any individual that consumes resources has an effect on the fitness of all other individuals competing for the same resources. Denote by x_{ij} the trait value of the j -th individual belonging to species i . The set of trait values across all individuals in the community at time $t \geq 0$ is written $X = \{x_{ij}\}$. We denote by \mathcal{B}_{ij} a function that maps X to the cumulative effect of all competitive interactions on the fitness of the j -th individual in species i . Since individuals do not compete with themselves the net multiplicative effects on fitness of both interspecific and intraspecific competition on the j -th individual in species i can be summarized by

$$\mathcal{B}_{ij}(X) = C_i^{\sum_{l \neq j} \mathcal{O}_{ii}(x_{ij}-x_{il}) + \sum_{k \neq i} \sum_{l=1}^{n_k} \mathcal{O}_{ik}(x_{ij}-x_{kl})}, \quad (142)$$

where \mathcal{O}_{ij} , defined in the main text, measures the overlap in resource use between individuals of species i and j as a function of their niche-centers. Writing $\mathcal{W}_{ij}(X)$ as the average number of offspring left by the j -th individual of species i , we have

$$\mathcal{W}_{ij}(X) = \mathcal{A}_i(x_{ij}) \mathcal{B}_{ij}(X), \quad (143)$$

where $\mathcal{A}_i(x) = \int_{\mathbb{R}} e_i(\zeta) u_i(\zeta, x) d\zeta$ accounts for abiotic selection and e_i has been defined in the main text.

We now turn to a diffusion limit. Since we have more than one population, we take the diffusion limit for each population one at a time starting with population 1. We write $\mathbf{n} = (n_1, \dots, n_S)$. Following Méléard and Roelly (1993, 1992) we rescale generation time and individual mass to $\frac{1}{n_1}$ and mean of the reproductive law to

$$\mathcal{W}_{1j}^{(\mathbf{n})}(X) = \mathcal{A}_1(x_{1j})^{1/n_1} \exp \left(\frac{\ln C_1}{n_1^2} \sum_{l \neq j} \mathcal{O}_{11}(x_{1j} - x_{1l}) + \frac{\ln C_1}{n_1} \sum_{k \neq 1} \frac{1}{n_k} \sum_{l=1}^{n_k} \mathcal{O}_{1k}(x_{1j} - x_{kl}) \right). \quad (144)$$

For large n_1 , we have the approximation

$$\mathcal{W}_{1j}^{(\mathbf{n})}(X) \approx \mathcal{A}_1(x_{1j})^{1/n_1} \left(1 + \frac{\ln C_1}{n_1^2} \sum_{l \neq j} \mathcal{O}_{11}(x_{1j} - x_{1l}) + \frac{\ln C_1}{n_1} \sum_{k \neq 1} \frac{1}{n_k} \sum_{l=1}^{n_k} \mathcal{O}_{1k}(x_{1j} - x_{kl}) \right). \quad (145)$$

Hence

$$\lim_{n_1 \rightarrow \infty} n_1 \left(\mathcal{W}_{1j}^{(\mathbf{n})}(X) - 1 \right) = \ln \mathcal{A}_1(x_{1j}) + \left(\int_{\mathbb{R}} \mathcal{O}_{11}(x_{1j} - y) \nu_1(y, t) dy + \sum_{k \neq 1} \frac{1}{n_k} \sum_{l=1}^{n_k} \mathcal{O}_{1k}(x_{1j} - x_{kl}) \right) \ln C_1. \quad (146)$$

We write $\lim_{\mathbf{n} \rightarrow \infty}$ for the iterated limit $\lim_{n_S \rightarrow \infty} \dots \lim_{n_1 \rightarrow \infty}$ and, assuming $\nu_i(\cdot, t) \in C_1^+(\mathbb{R})$ for $i = 1, \dots, S$ and $t \in [0, \infty)$, we set $\boldsymbol{\nu} = (\nu_1, \dots, \nu_S)$. Then, for any $\boldsymbol{\nu}$, the diffusion limits for the remaining populations provides the Malthusian parameter for individuals in species i with trait value x_{1j} as

$$m_1(\boldsymbol{\nu}, x_{1j}) := \lim_{\mathbf{n} \rightarrow \infty} n_1 \left(\mathcal{W}_{1j}^{(\mathbf{n})}(X) - 1 \right) = \ln \mathcal{A}_1(x) + \left(\sum_{k=1}^S \int_{\mathbb{R}} \mathcal{O}_{1k}(x_{1j} - y) \nu_k(y, t) dy \right) \ln C_1. \quad (147)$$

We compute the average niche overlap of an individual in species i with niche location x across all individuals in species j as

$$\bar{\mathcal{O}}_{ij}(x, t) = \frac{\int_{\mathbb{R}} \mathcal{O}_{ij}(x - y) \nu_j(y, t) dy}{\int_{\mathbb{R}} \nu_j(y, t) dy}. \quad (148)$$

1278 We now assume the resource utilization curves $u_i(\zeta)$ and phenotypic densities $\nu_i(x, t)$ are Gaussian curves
 1279 for $i = 1, \dots, S$. In this case $\bar{\mathcal{O}}_{ij}(x, t)$ simplifies to

$$\bar{\mathcal{O}}_{ij}(x, t) = \frac{\int_{\mathbb{R}} \mathcal{O}_{ij}(x - y) \nu_j(y, t) dy}{\int_{\mathbb{R}} \nu_j(y, t) dy} = \frac{U_i U_j}{\sqrt{2\pi(w_i + w_j + \sigma_j^2(t))}} \exp\left(-\frac{(x - \bar{x}_j(t))^2}{2(w_i + w_j + \sigma_j^2(t))}\right). \quad (149)$$

1280 Setting

$$\sigma_i^2(t) = G_i(t) + \eta_i, \quad (150a)$$

$$R_i = \ln\left(\frac{Q_i U_i}{\sqrt{1 + A_i w_i}}\right), \quad (150b)$$

$$a_i = \frac{A_i}{1 + A_i w_i}, \quad (150c)$$

$$\tilde{b}_{ij}(t) = \frac{1}{w_i + w_j + \sigma_j^2(t)}, \quad (150d)$$

$$c_i = -\ln C_i, \quad (150e)$$

1281 we get

$$m_i(\boldsymbol{\nu}, x) = R_i - \frac{a_i}{2}(x - \theta_i)^2 - c_i \sum_{j=1}^S N_j(t) U_i U_j \sqrt{\frac{\tilde{b}_{ij}(t)}{2\pi}} e^{-\frac{\tilde{b}_{ij}(t)}{2}(x - \bar{x}_j(t))^2}. \quad (151)$$

1282 Hence, our fitness function is bounded above, as required in the main text.

1283 For the remainder of the derivation we suppress notation indicating dependency on $\boldsymbol{\nu}$, x and t . From (151)
 1284 we calculate

$$\frac{\partial m_i}{\partial \bar{x}_i} = c_i N_i U_i^2 \tilde{b}_{ii}(x - \bar{x}_i) \sqrt{\frac{\tilde{b}_{ii}}{2\pi}} e^{-\frac{\tilde{b}_{ii}}{2}(x - \bar{x}_i)^2} \quad (152)$$

$$\begin{aligned} \frac{\partial m_i}{\partial G_i} &= \frac{c_i N_i U_i^2}{2} \left(\frac{(x - \bar{x}_i)^2 - G_i - \eta_i - 2w_i}{(G_i + \eta_i + 2w_i)^2} \right) \sqrt{\frac{\tilde{b}_{ii}}{2\pi}} e^{-\frac{\tilde{b}_{ii}}{2}(x - \bar{x}_i)^2} \\ &= \frac{c_i N_i U_i^2 \tilde{b}_{ii}^2}{2} ((x - \bar{x}_i)^2 - \sigma_i^2 - 2w_i) \sqrt{\frac{\tilde{b}_{ii}}{2\pi}} e^{-\frac{\tilde{b}_{ii}}{2}(x - \bar{x}_i)^2}. \end{aligned} \quad (153)$$

1285 Note that

$$\begin{aligned} &\sqrt{\frac{\tilde{b}_{ii}}{2\pi}} \exp\left(-\frac{\tilde{b}_{ii}}{2}(x - \bar{x}_i)^2\right) \sqrt{\frac{1}{2\pi\sigma_i^2}} \exp\left(-\frac{(x - \bar{x}_i)^2}{2\sigma_i^2}\right) \\ &= \sqrt{\frac{1}{2\pi(\sigma_i^2 + 1/\tilde{b}_{ii})}} \sqrt{\frac{\sigma_i^2 + 1/\tilde{b}_{ii}}{2\pi\sigma_i^2/\tilde{b}_{ii}}} \exp\left(-\frac{\sigma_i^2 + 1/\tilde{b}_{ii}}{2\sigma_i^2/\tilde{b}_{ii}}(x - \bar{x}_i)^2\right) \\ &= \sqrt{\frac{1}{4\pi(\sigma_i^2 + w_i)}} \sqrt{\frac{2(\sigma_i^2 + w_i)}{2\pi\sigma_i^2(\sigma_i^2 + 2w_i)}} \exp\left(-\frac{\sigma_i^2(\sigma_i^2 + 2w_i)}{4(\sigma_i^2 + w_i)}(x - \bar{x}_i)^2\right). \end{aligned} \quad (154)$$

1286 Hence,

$$\frac{\overline{\partial m_i}}{\partial \bar{x}_i} = 0, \quad (155)$$

$$\begin{aligned} \frac{\overline{\partial m_i}}{\partial G_i} &= \frac{c_i N_i U_i^2}{2(\sigma_i^2 + 2w_i)^2} \left(\frac{(\sigma_i^2 + 2w_i)\sigma_i^2}{2(w_i + \sigma_i^2)} - \sigma_i^2 - 2w_i \right) \sqrt{\frac{b_{ii}}{2\pi}} \\ &= \frac{c_i N_i U_i^2}{2(\sigma_i^2 + 2w_i)} \left(\frac{\sigma_i^2}{2(\sigma_i^2 + w_i)} - 1 \right) \sqrt{\frac{b_{ii}}{2\pi}} = -\frac{c_i N_i U_i^2 b_{ii}}{2} \sqrt{\frac{b_{ii}}{2\pi}}, \end{aligned} \quad (156)$$

1287 where

$$b_{ij} = \frac{1}{w_i + w_j + \sigma_i^2 + \sigma_j^2}. \quad (157)$$

1288 The average fitness for species i is

$$\bar{m}_i = R_i - \frac{a_i}{2} \left((\bar{x}_i - \theta_i)^2 + G_i + \eta_i \right) - c_i \sum_{j=1}^S N_j U_i U_j \sqrt{\frac{b_{ij}}{2\pi}} e^{-\frac{b_{ij}}{2}(\bar{x}_i - \bar{x}_j)^2}. \quad (158)$$

1289 Thus,

$$\frac{\partial \bar{m}_i}{\partial \bar{x}_i} = a_i(\theta_i - \bar{x}_i) - c_i \sum_j N_j U_i U_j b_{ij}(\bar{x}_j - \bar{x}_i) \sqrt{\frac{b_{ij}}{2\pi}} e^{-\frac{b_{ij}}{2}(\bar{x}_i - \bar{x}_j)^2}, \quad (159)$$

$$\frac{\partial \bar{m}_i}{\partial G_i} = -\frac{a_i}{2} + \frac{c_i}{2} \sum_{j=1}^S N_j U_i U_j b_{ij} (1 - b_{ij}(\bar{x}_i - \bar{x}_j)^2) \sqrt{\frac{b_{ij}}{2\pi}} e^{-\frac{b_{ij}}{2}(\bar{x}_i - \bar{x}_j)^2}. \quad (160)$$

1290 In particular

$$\frac{\partial \bar{m}_i}{\partial G_i} - \frac{\overline{\partial m_i}}{\partial G_i} = -\frac{a_i}{2} + \frac{c_i}{2} \left(N_i U_i^2 b_{ii} \sqrt{\frac{b_{ii}}{2\pi}} + \sum_{j=1}^S N_j U_i U_j b_{ij} (1 - b_{ij}(\bar{x}_i - \bar{x}_j)^2) \sqrt{\frac{b_{ij}}{2\pi}} e^{-\frac{b_{ij}}{2}(\bar{x}_i - \bar{x}_j)^2} \right). \quad (161)$$

1291 Applying equations (36a), (46a) and (46b) of the main text recovers system (51) of the main text.

1292 **5.12 The relation between competition coefficients and selection**

1293 **5.12.1 Derivation of analytical approximations**

1294 Just as with most calculations in this work, the derivations are straightforward applications of Gaussian
1295 products. That is, if

$$f_1(x) = \frac{1}{\sqrt{2\pi\sigma_1^2}} \exp\left(-\frac{(\mu_1 - x)^2}{2\sigma_1^2}\right), \quad f_2(x) = \frac{1}{\sqrt{2\pi\sigma_2^2}} \exp\left(-\frac{(\mu_2 - x)^2}{2\sigma_2^2}\right), \quad (162)$$

1296 then

$$f_1(x)f_2(x) = \frac{1}{\sqrt{2\pi(\sigma_1^2 + \sigma_2^2)}} \exp\left(-\frac{(\mu_1 - \mu_2)^2}{2(\sigma_1^2 + \sigma_2^2)}\right) \frac{1}{\sqrt{2\pi\tilde{\sigma}^2}} \exp\left(-\frac{(\tilde{\mu} - x)^2}{2\tilde{\sigma}^2}\right), \quad (163)$$

1297 where

$$\tilde{\mu} = \frac{\sigma_2^2\mu_1 + \sigma_1^2\mu_2}{\sigma_1^2 + \sigma_2^2}, \quad \tilde{\sigma}^2 = \frac{\sigma_1^2\sigma_2^2}{\sigma_1^2 + \sigma_2^2}. \quad (164)$$

1298 **5.12.1.1 Caclulating $\text{Cov}_{f_{\bar{X}}}(\alpha, \gamma)$**

1299 Recalling

$$\alpha(\bar{x}_i, \bar{x}_j) = \frac{c}{\bar{r}} \sqrt{\frac{b}{2\pi}} \exp\left(-\frac{b}{2}(\bar{x}_i - \bar{x}_j)^2\right), \quad (165)$$

$$\gamma(\bar{x}_i, \bar{x}_j) = cNb \left(1 - b(\bar{x}_i - \bar{x}_j)^2\right) \sqrt{\frac{b}{2\pi}} \exp\left(-\frac{b}{2}(\bar{x}_i - \bar{x}_j)^2\right), \quad (166)$$

1300 we have

$$\begin{aligned} \bar{\alpha} &= \int_{\mathbb{R}} \int_{\mathbb{R}} \alpha(\bar{x}_i, \bar{x}_j) f_{\bar{X}}(\bar{x}_i) f_{\bar{X}}(\bar{x}_j) d\bar{x}_i d\bar{x}_j \\ &= \frac{c}{\bar{r}} \int_{\mathbb{R}} \frac{1}{\sqrt{2\pi(b^{-1} + V_{\bar{X}})}} \exp\left(-\frac{(\bar{x} - \bar{x}_j)^2}{2(b^{-1} + V_{\bar{X}})}\right) f_{\bar{X}}(\bar{x}_j) d\bar{x}_j = \frac{c/\bar{r}}{\sqrt{2\pi(b^{-1} + 2V_{\bar{X}})}}, \end{aligned} \quad (167)$$

$$\begin{aligned} \bar{\gamma} &= \int_{\mathbb{R}} \int_{\mathbb{R}} \gamma(\bar{x}_i, \bar{x}_j) f_{\bar{X}}(\bar{x}_i) f_{\bar{X}}(\bar{x}_j) d\bar{x}_i d\bar{x}_j \\ &= cNb \int_{\mathbb{R}} \left\{ 1 - \left[\left(\frac{\bar{x} + bV_{\bar{X}}\bar{x}_j}{1 + bV_{\bar{X}}} - \bar{x}_j \right)^2 + \frac{V_{\bar{X}}}{1 + bV_{\bar{X}}} \right] \right\} \frac{1}{\sqrt{2\pi(b^{-1} + V_{\bar{X}})}} \exp\left(-\frac{(\bar{x} - \bar{x}_j)^2}{2(b^{-1} + V_{\bar{X}})}\right) f_{\bar{X}}(\bar{x}_j) d\bar{x}_j \\ &= cNb \int_{\mathbb{R}} \left\{ 1 - \left[\left(\frac{\bar{x} - \bar{x}_j}{1 + bV_{\bar{X}}} \right)^2 + \frac{V_{\bar{X}}}{1 + bV_{\bar{X}}} \right] \right\} \frac{1}{\sqrt{2\pi(b^{-1} + V_{\bar{X}})}} \exp\left(-\frac{(\bar{x} - \bar{x}_j)^2}{2(b^{-1} + V_{\bar{X}})}\right) f_{\bar{X}}(\bar{x}_j) d\bar{x}_j \\ &= cNb \left(1 - \frac{(1 + bV_{\bar{X}})V_{\bar{X}}}{1 + 2bV_{\bar{X}}} \frac{1}{(1 + bV_{\bar{X}})^2} - \frac{V_{\bar{X}}}{1 + bV_{\bar{X}}} \right) \frac{1}{\sqrt{2\pi(b^{-1} + 2V_{\bar{X}})}} \\ &= cNb \left[1 - \left(\frac{1}{1 + 2bV_{\bar{X}}} + 1 \right) \frac{V_{\bar{X}}}{1 + bV_{\bar{X}}} \right] \frac{1}{\sqrt{2\pi(b^{-1} + 2V_{\bar{X}})}} \\ &= cNb \left(1 - \frac{2V_{\bar{X}}}{1 + 2bV_{\bar{X}}} \right) \sqrt{\frac{b}{2\pi(1 + 2bV_{\bar{X}})}}, \end{aligned} \quad (168)$$

$$\begin{aligned}
\text{Var}_{f_{\bar{X}}}(\alpha) &= \int_{\mathbb{R}} \int_{\mathbb{R}} (\bar{\alpha} - \alpha(\bar{x}_i, \bar{x}_j))^2 f_{\bar{X}}(\bar{x}_i) f_{\bar{X}}(\bar{x}_j) d\bar{x}_i d\bar{x}_j \\
&= \frac{c^2}{\bar{r}^2} \left(\sqrt{\frac{b}{4\pi}} \int_{\mathbb{R}} \int_{\mathbb{R}} \sqrt{\frac{b}{\pi}} \exp(-b(\bar{x}_i - \bar{x}_j)^2) f_{\bar{X}}(\bar{x}_i) f_{\bar{X}}(\bar{x}_j) d\bar{x}_i d\bar{x}_j - \frac{1}{2\pi(b^{-1} + 2V_{\bar{X}})} \right) \\
&= \frac{c^2}{\bar{r}^2} \left(\sqrt{\frac{b}{4\pi}} \int_{\mathbb{R}} \sqrt{\frac{1}{2\pi(\frac{1}{2b} + V_{\bar{X}})}} \exp(-b(\bar{x} - \bar{x}_j)^2) f_{\bar{X}}(\bar{x}_j) d\bar{x}_j - \frac{1}{2\pi(b^{-1} + 2V_{\bar{X}})} \right) \\
&= \frac{c^2}{\bar{r}^2} \left(\sqrt{\frac{b}{4\pi}} \sqrt{\frac{1}{2\pi(\frac{1}{2b} + 2V_{\bar{X}})}} - \frac{1}{2\pi(b^{-1} + 2V_{\bar{X}})} \right) = \frac{c^2 b}{2\pi \bar{r}^2} \left(\frac{1}{\sqrt{1 + 4bV_{\bar{X}}}} - \frac{1}{1 + 2bV_{\bar{X}}} \right), \quad (169)
\end{aligned}$$

$$\begin{aligned}
\text{Cov}_{f_{\bar{X}}}(\alpha, \gamma) &= \int_{\mathbb{R}} \int_{\mathbb{R}} (\bar{\alpha} - \alpha(\bar{x}_i, \bar{x}_j)) (\bar{\gamma} - \gamma(\bar{x}_i, \bar{x}_j)) f_{\bar{X}}(\bar{x}_i) f_{\bar{X}}(\bar{x}_j) d\bar{x}_i d\bar{x}_j \\
&= \frac{c^2 N b}{2\bar{r}} \sqrt{\frac{b}{\pi}} \int_{\mathbb{R}} \int_{\mathbb{R}} (1 - b(\bar{x}_i - \bar{x}_j)^2) \sqrt{\frac{b}{\pi}} \exp(-b(\bar{x}_i - \bar{x}_j)^2) f_{\bar{X}}(\bar{x}_i) f_{\bar{X}}(\bar{x}_j) d\bar{x}_i d\bar{x}_j - \bar{\alpha} \bar{\gamma} \\
&= \frac{c^2 N b}{2\bar{r}} \sqrt{\frac{b}{\pi}} \frac{1 - 2bV_{\bar{X}}}{\sqrt{2\pi((2b)^{-1} + 2V_{\bar{X}})}} - \frac{c^2 N b}{\bar{r}} \frac{1 - 2bV_{\bar{X}}}{2\pi(b^{-1} + 2V_{\bar{X}})} \\
&= \frac{c^2 b^2 N}{2\pi \bar{r}} (1 - 2bV_{\bar{X}}) \left(\frac{1}{\sqrt{1 + 4bV_{\bar{X}}}} - \frac{1}{1 + 2bV_{\bar{X}}} \right). \quad (170)
\end{aligned}$$

5.12.1.2 Caclulating $\text{Cov}_{f_{\bar{X}}}(\alpha, |\beta|)$

To calculate moments of $|\beta|$ we note that, as a random variable, $|\beta|$ takes a folded normal distribution. Setting $\Phi(x)$ equal to the cumulative density function of the standard normal distribution and using the properties of the folded normal distribution, we find

$$|\bar{\beta}| = \sqrt{\frac{2\text{Var}_{f_{\bar{X}}}(\beta)}{\pi}} \exp\left(-\frac{\bar{\beta}^2}{2\text{Var}_{f_{\bar{X}}}(\beta)}\right) - \bar{\beta} \left[1 - 2\Phi\left(\frac{\bar{\beta}}{\sqrt{\text{Var}_{f_{\bar{X}}}(\beta)}}\right)\right] \quad (171)$$

$$\text{Var}_{f_{\bar{X}}}(|\beta|) = \bar{\beta}^2 + \text{Var}_{f_{\bar{X}}}(\beta) - |\bar{\beta}|^2. \quad (172)$$

Recall that

$$\beta(\bar{x}_i, \bar{x}_j) = cNb(\bar{x}_i - \bar{x}_j) \sqrt{\frac{b}{2\pi}} \exp\left(-\frac{b}{2}(\bar{x}_i - \bar{x}_j)^2\right) \quad (173)$$

and hence

$$\begin{aligned}
\bar{\beta} &= \int_{\mathbb{R}} \int_{\mathbb{R}} \beta(\bar{x}_i, \bar{x}_j) f_{\bar{X}}(\bar{x}_i) f_{\bar{X}}(\bar{x}_j) d\bar{x}_i d\bar{x}_j \\
&= cNb \int_{\mathbb{R}} (\bar{x} - \bar{x}_j) \frac{1}{\sqrt{2\pi(b^{-1} + V_{\bar{X}})}} \exp\left(-\frac{(\bar{x} - \bar{x}_j)^2}{2(b^{-1} + V_{\bar{X}})}\right) f_{\bar{X}}(\bar{x}_j) d\bar{x}_j = 0, \quad (174)
\end{aligned}$$

$$\begin{aligned}
\text{Var}_{f_{\bar{X}}}(\beta) &= \int_{\mathbb{R}} \int_{\mathbb{R}} (\bar{\beta} - \beta(\bar{x}_i, \bar{x}_j))^2 f_{\bar{X}}(\bar{x}_i) f_{\bar{X}}(\bar{x}_j) d\bar{x}_i d\bar{x}_j \\
&= \int_{\mathbb{R}} \int_{\mathbb{R}} c^2 N^2 b^2 (\bar{x}_i - \bar{x}_j)^2 \frac{b}{2\pi} \exp(-b(\bar{x}_i - \bar{x}_j)^2) f_{\bar{X}}(\bar{x}_i) f_{\bar{X}}(\bar{x}_j) d\bar{x}_i d\bar{x}_j \\
&= \sqrt{\frac{b}{4\pi}} c^2 N^2 b^2 \int_{\mathbb{R}} \left[\left(\frac{\bar{x} + 2bV_{\bar{X}}\bar{x}_j}{1 + 2bV_{\bar{X}}} - \bar{x}_j \right)^2 + \frac{V_{\bar{X}}}{1 + 2bV_{\bar{X}}} \right] \frac{\exp\left(-\frac{(\bar{x} - \bar{x}_j)^2}{2(\frac{1}{2b} + V_{\bar{X}})}\right)}{\sqrt{2\pi(\frac{1}{2b} + V_{\bar{X}})}} f_{\bar{X}}(\bar{x}_j) d\bar{x}_j \\
&= \sqrt{\frac{b}{4\pi}} c^2 N^2 b^2 \int_{\mathbb{R}} \left[\frac{(\bar{x} - \bar{x}_j)^2}{(1 + 2bV_{\bar{X}})^2} + \frac{V_{\bar{X}}}{1 + 2bV_{\bar{X}}} \right] \frac{\exp\left(-\frac{(\bar{x} - \bar{x}_j)^2}{2(\frac{1}{2b} + V_{\bar{X}})}\right)}{\sqrt{2\pi(\frac{1}{2b} + V_{\bar{X}})}} f_{\bar{X}}(\bar{x}_j) d\bar{x}_j \\
&= \sqrt{\frac{b}{4\pi}} c^2 N^2 b^2 \left[\frac{(1 + 2bV_{\bar{X}})V_{\bar{X}}}{1 + 4bV_{\bar{X}}} \frac{1}{(1 + 2bV_{\bar{X}})^2} + \frac{V_{\bar{X}}}{1 + 2bV_{\bar{X}}} \right] \frac{1}{\sqrt{2\pi(\frac{1}{2b} + 2V_{\bar{X}})}} \\
&= \frac{b}{\pi} \frac{c^2 N^2 b^2}{\sqrt{1 + 4bV_{\bar{X}}}} \frac{V_{\bar{X}}}{1 + 2bV_{\bar{X}}} \left(\frac{1}{1 + 4bV_{\bar{X}}} + 1 \right) = \frac{2c^2 N^2 b^3 V_{\bar{X}}}{\pi(1 + 4bV_{\bar{X}})^{3/2}}. \quad (175)
\end{aligned}$$

1307 Thus, using properties of the folded normal distribution, we find

$$|\bar{\beta}| = \sqrt{\frac{2}{\pi}} \frac{cNb^{3/2}}{(1 + 4bV_{\bar{X}})^{3/4}} \sqrt{\frac{2V_{\bar{X}}}{\pi}} = \frac{2}{\pi} \frac{cNb^{3/2}}{(1 + 4bV_{\bar{X}})^{3/4}} \sqrt{V_{\bar{X}}}, \quad (176)$$

$$\text{Var}_{f_{\bar{X}}}(|\beta|) = \frac{c^2 N^2 b^3}{(1 + 4bV_{\bar{X}})^{3/2}} \frac{2V_{\bar{X}}}{\pi} \left(1 - \frac{2}{\pi} \right). \quad (177)$$

1308 We also calculate

$$\begin{aligned}
\text{Cov}_{f_{\bar{X}}}(\alpha, \beta) &= \int_{\mathbb{R}} \int_{\mathbb{R}} (\bar{\alpha} - \alpha(\bar{x}_i, \bar{x}_j))(\bar{\beta} - \beta(\bar{x}_i, \bar{x}_j)) f_{\bar{X}}(\bar{x}_i) f_{\bar{X}}(\bar{x}_j) d\bar{x}_i d\bar{x}_j \\
&= \frac{c^2 Nb}{2\bar{r}} \sqrt{\frac{b}{\pi}} \int_{\mathbb{R}} \int_{\mathbb{R}} (\bar{x}_i - \bar{x}_j) \sqrt{\frac{b}{\pi}} \exp(-b(\bar{x}_i - \bar{x}_j)^2) f_{\bar{X}}(\bar{x}_i) f_{\bar{X}}(\bar{x}_j) d\bar{x}_i d\bar{x}_j = 0. \quad (178)
\end{aligned}$$

1309 In attempt to calculate $\text{Cov}_{f_{\bar{X}}}(\alpha, |\beta|)$ we find

$$\begin{aligned}
\text{Cov}_{f_{\bar{X}}}(\alpha, |\beta|) &= \int_{\mathbb{R}} \int_{\mathbb{R}} \alpha(\bar{x}_i, \bar{x}_j) |\beta(\bar{x}_i, \bar{x}_j)| f_{\bar{X}}(\bar{x}_i) f_{\bar{X}}(\bar{x}_j) d\bar{x}_i d\bar{x}_j - \bar{\alpha} |\bar{\beta}| \\
&= \int_{\mathbb{R}} \int_{\mathbb{R}} \frac{c}{\bar{r}} \sqrt{\frac{b}{2\pi}} \exp\left(-\frac{b}{2}(\bar{x}_i - \bar{x}_j)^2\right) cNb |\bar{x}_i - \bar{x}_j| \sqrt{\frac{b}{2\pi}} \exp\left(-\frac{b}{2}(\bar{x}_i - \bar{x}_j)^2\right) f_{\bar{X}}(\bar{x}_i) f_{\bar{X}}(\bar{x}_j) d\bar{x}_i d\bar{x}_j - \bar{\alpha} |\bar{\beta}| \\
&= \frac{c^2 Nb}{\bar{r}} \sqrt{\frac{b}{4\pi}} \int_{\mathbb{R}} \int_{\mathbb{R}} |\bar{x}_i - \bar{x}_j| \sqrt{\frac{b}{\pi}} \exp(-b(\bar{x}_i - \bar{x}_j)^2) f_{\bar{X}}(\bar{x}_i) f_{\bar{X}}(\bar{x}_j) d\bar{x}_i d\bar{x}_j - \bar{\alpha} |\bar{\beta}|. \quad (179)
\end{aligned}$$

1310 Just as we used the folded normal to find $|\bar{\beta}|$ and $\text{Var}_{f_{\bar{X}}}(|\beta|)$, we can calculate $\text{Cov}_{f_{\bar{X}}}(\alpha, |\beta|)$ by considering

$$\int_{\mathbb{R}} \int_{\mathbb{R}} (\bar{x}_i - \bar{x}_j) \sqrt{\frac{b}{\pi}} \exp(-b(\bar{x}_i - \bar{x}_j)^2) f_{\bar{X}}(\bar{x}_i) f_{\bar{X}}(\bar{x}_j) d\bar{x}_i d\bar{x}_j = 0 \quad (180)$$

1311 and

$$\begin{aligned}
& \int_{\mathbb{R}} \int_{\mathbb{R}} (\bar{x}_i - \bar{x}_j)^2 \frac{b}{\pi} \exp(-2b(\bar{x}_i - \bar{x}_j)^2) f_{\bar{X}}(\bar{x}_i) f_{\bar{X}}(\bar{x}_j) d\bar{x}_i d\bar{x}_j \\
&= \sqrt{\frac{2b}{\pi}} \int_{\mathbb{R}} \int_{\mathbb{R}} (\bar{x}_i - \bar{x}_j)^2 \frac{1}{\sqrt{2\pi \frac{1}{4b}}} \exp\left(-\frac{(\bar{x}_i - \bar{x}_j)^2}{2 \frac{1}{4b}}\right) f_{\bar{X}}(\bar{x}_i) f_{\bar{X}}(\bar{x}_j) d\bar{x}_i d\bar{x}_j \\
&= \sqrt{\frac{2b}{\pi}} \int_{\mathbb{R}} \left[\left(\frac{\bar{x} + 4bV_{\bar{X}}\bar{x}_j}{1 + 4bV_{\bar{X}}} - \bar{x}_j \right)^2 + \frac{V_{\bar{X}}}{1 + 4bV_{\bar{X}}} \right] \frac{1}{\sqrt{2\pi(\frac{1}{4b} + V_{\bar{X}})}} \exp\left(-\frac{(\bar{x} - \bar{x}_j)^2}{2(\frac{1}{4b} + V_{\bar{X}})}\right) f_{\bar{X}}(\bar{x}_j) d\bar{x}_j \\
&= \sqrt{\frac{2b}{\pi}} \int_{\mathbb{R}} \left[\left(\frac{\bar{x} - \bar{x}_j}{1 + 4bV_{\bar{X}}} \right)^2 + \frac{V_{\bar{X}}}{1 + 4bV_{\bar{X}}} \right] \frac{1}{\sqrt{2\pi(\frac{1}{4b} + V_{\bar{X}})}} \exp\left(-\frac{(\bar{x} - \bar{x}_j)^2}{2(\frac{1}{4b} + V_{\bar{X}})}\right) f_{\bar{X}}(\bar{x}_j) d\bar{x}_j \\
&= \sqrt{\frac{2b}{\pi}} \left[\frac{(1 + 4bV_{\bar{X}})V_{\bar{X}}}{1 + 8bV_{\bar{X}}} \frac{1}{(1 + 4bV_{\bar{X}})^2} + \frac{V_{\bar{X}}}{1 + 4bV_{\bar{X}}} \right] \frac{1}{\sqrt{2\pi(\frac{1}{4b} + 2V_{\bar{X}})}} \\
&= \sqrt{\frac{2b}{\pi}} \frac{2V_{\bar{X}}}{1 + 8bV_{\bar{X}}} \sqrt{\frac{4b}{2\pi(1 + 8bV_{\bar{X}})}} = \frac{b}{\pi} \frac{4V_{\bar{X}}}{(1 + 8bV_{\bar{X}})^{3/2}}. \quad (181)
\end{aligned}$$

1312 Hence

$$\int_{\mathbb{R}} \int_{\mathbb{R}} |\bar{x}_i - \bar{x}_j| \sqrt{\frac{b}{\pi}} \exp(-b(\bar{x}_i - \bar{x}_j)^2) f_{\bar{X}}(\bar{x}_i) f_{\bar{X}}(\bar{x}_j) d\bar{x}_i d\bar{x}_j = \sqrt{\frac{2}{\pi}} \sqrt{\frac{b}{\pi} \frac{4V_{\bar{X}}}{(1 + 8bV_{\bar{X}})^{3/2}}} = \frac{2}{\pi} \frac{\sqrt{2bV_{\bar{X}}}}{(1 + 8bV_{\bar{X}})^{3/4}} \quad (182)$$

1313 and

$$\begin{aligned}
\text{Cov}_{f_{\bar{X}}}(\alpha, |\beta|) &= \frac{c^2 N b}{\bar{r}} \sqrt{\frac{b}{4\pi}} \frac{2}{\pi} \frac{\sqrt{2bV_{\bar{X}}}}{(1 + 8bV_{\bar{X}})^{3/4}} - \bar{\alpha} |\beta| \\
&= \frac{2c^2 N b^2}{\pi \bar{r} (1 + 8bV_{\bar{X}})^{3/4}} \sqrt{\frac{V_{\bar{X}}}{2\pi}} - \frac{c}{\bar{r}} \sqrt{\frac{b}{2\pi(1 + 2bV_{\bar{X}})}} \frac{2}{\pi} \frac{c N b^{3/2}}{(1 + 4bV_{\bar{X}})^{3/4}} \sqrt{V_{\bar{X}}} \\
&= \frac{2c^2 N b^2}{\pi \bar{r} (1 + 8bV_{\bar{X}})^{3/4}} \sqrt{\frac{V_{\bar{X}}}{2\pi}} - \frac{2c^2 N b^2}{\pi \bar{r} (1 + 4bV_{\bar{X}})^{3/4}} \sqrt{\frac{V_{\bar{X}}}{2\pi(1 + 2bV_{\bar{X}})}} \\
&= \frac{2c^2 N b^2}{\pi \bar{r}} \sqrt{\frac{V_{\bar{X}}}{2\pi}} \left(\frac{1}{(1 + 8bV_{\bar{X}})^{3/4}} - \frac{1}{(1 + 4bV_{\bar{X}})^{3/4} (1 + 2bV_{\bar{X}})^{1/2}} \right). \quad (183)
\end{aligned}$$

1314 **5.12.1.3 Starting the caclulation of $\text{Cov}_{f_{\bar{X}}}(\alpha, \mathfrak{C})$**

1315 We have

$$\mathfrak{C}(\bar{x}_i, \bar{x}_j) = c^2 N^2 b^2 \left(|\bar{x}_i - \bar{x}_j| + |1 - b(\bar{x}_i - \bar{x}_j)^2| \right)^2 \exp\left(-\frac{b}{2}(\bar{x}_i - \bar{x}_j)^2\right). \quad (184)$$

1316 Note that the random variable $\delta = \bar{x}_i - \bar{x}_j$ is a mean zero Gaussian random variable with variance $2V_{\bar{X}}$. We
1317 write the probability density function of δ as $f_{\Delta}(\delta)$. Substituting in δ , we can write

$$\begin{aligned}\mathfrak{C}(\delta, 0) &= c^2 N^2 b^2 \left(|\delta| + |1 - b\delta^2| \right)^2 \exp\left(-\frac{b}{2}\delta^2\right) \\ &= c^2 N^2 b^2 \left(\delta^2 + 2|\delta| - b|\delta|^3 + (1 - b\delta^2)^2 \right) \exp\left(-\frac{b}{2}\delta^2\right). \quad (185)\end{aligned}$$

From this expression, we see properties of the folded normal distribution can be used to calculate several components of the integral $\text{Cov}_{f_{\bar{X}}}(\alpha, \mathfrak{C})$, but a major technical challenge lies in calculating

$$\int_{\mathbb{R}} ||\delta| - b|\delta|^3| \exp\left(-\frac{b}{2}\delta^2\right) f_{\Delta}(\delta) d\delta. \quad (186)$$

Instead of overcoming this challenge to find an analytical form of $\text{Cov}_{f_{\bar{X}}}(\alpha, \mathfrak{C})$ we turn to a numerical approach outlined in the following section.

5.12.2 Numerical estimates for heterogeneous N and G

Figure 7: Numerical estimate for the correlations of selection gradients and competition coefficients.

Details on simulations, table of parameters, distributions of a and c .
